Abstract
Harpin, a bacterial protein that elicits systemic acquired resistance increasing plant disease resistance in several species, is reported to enhance yield and quality of several crops including corn (Zea may L.). This experiment examined the effect of Harpin on corn yield, suppression of aflatoxin and fumonisins contamination, and Aspergillus colonization in corn grain. The experiment was conducted in 2002 and 2003 on two different soils at Stoneville, MS. Plots of a commercial corn hybrid were inoculated with Aspergillus flavus strain F3W4, formulated on autoclaved wheat (Triticum aestivum L) kernels, and applied to the soil surface at growth stages V5-V6 of the corn. Fusarium verticillioides was allowed to infect the grain naturally. Harpin was applied at a rate of 160 g/ha as a spray over the top of corn plants at growth stages V1 to V2 and again at V5 to V6. No differences in yield were observed nor did harpin have any effect on aflatoxin or fumonisins contamination. Aspergillus colonization was unaffected by harpin at one site and was lower than the untreated controls when applied at growth stages V1 to V2 at the other.

Introduction
Harpin, a bacterial protein sold under the trade name Messenger (Eden Bioscience, Bothell, WA), is reported to increase yields in corn, rice (Oryza sativa L.), cotton (Gossypium hirsutum L.), tomatoes (Lycopersicon esculentum Mill.), strawberry (Fragaria virginiana Duchesne), and grapes (Vitis spp.) (12,13,24,25,26). The active ingredient was first isolated from Erwinia amylovora (14,25). In higher plants, harpin causes a hypersensitive response that results in disease resistance (5,17). It has also been shown to stimulate growth in some plant species, increasing size and accelerating the rate of development (17).

Harpin is thought to protect plants against disease by stimulating an induced resistance. Harpin has been demonstrated to increase resistance of tobacco (Nicotiana tabacum L.) plants to tobacco mosaic virus (27) and Arabidopsis plants to Pseudomonas syringae (10,11). Genetic resistance to fungal, bacterial, nematode, and viral infections are also induced by harpin (6,21,25,27). In one study, harpin application was noted to increase plant growth (12,13). In field trials, this effect on growth has resulted in higher yields (12). Also, researchers at Eden Bioscience, the makers of Messenger, claim that it consistently increases several physiological processes in a variety of crops such as photosynthesis and nutrient uptake (12).

Economic losses in corn caused by Aspergillus and Fusarium ear rots (3,16,18) can be large, in part because of the production of aflatoxin and fumonisins by these respective species (20). Corn grain contaminated by these fungi and their respective mycotoxins can cause toxicological problems for livestock (1,8). Federal guidelines by the FDA prohibit the use of corn with aflatoxin greater than 20 ppb (23) and fumonisins greater than 2 ppm (22).

The objectives of this study were to determine if harpin could increase corn yields, suppress aflatoxin and fumonisins contamination of the grain, and Aspergillus colonization in corn grain.
Treatment of Corn with Harpin

The corn hybrid Pioneer 32R25, was planted at two sites on Mississippi State University’s Delta Branch Experiment Station near Stoneville, MS. Site 1 was on a Dundee silty clay soil (fine-silty, mixed, thermic Aeric Ochraqualfs) prepared for planting by forming 40-cm ridges spaced 76 cm apart. Site 2 was a Beulah fine sandy loam soil (coarse-loamy, mixed thermic Typic Dystrochrepts) prepared for planting by forming 50-cm ridges spaced 102 cm apart. Planting occurred on 19 April 2002 and 16 April 2003 at both sites. The experimental design was a randomized complete block replicated four times. Individual plots were six rows 9 m long and eight rows 18 m long for Sites 1 and 2, respectively.

Approximately 56 kg of K per ha as murate potash and 112 kg of N per ha as NH₄NO₃ were applied pre-plant, followed by an additional 112 kg of N per ha of N as NH₄NO₃: urea liquid formulation at growth stage V6 (19). Weeds were controlled by application of the herbicide Permit (halosulfuron, Monsanto, St Louis, MO) at 93 g/ha to Site 1 and Bicep II (atrazine + metolachlor, Monsanto Co., St. Louis, MO), at 4.7 liter/ha to Site 2. Furrow irrigation at the rate of approximately 25 mm per irrigation, was applied at both sites in 2002 and 2003 beginning at growth stage R1 using a schedule previously defined (7). Plant populations in both fields were achieved by over planting 200% and then thinning to a density of ~ 71,500 plants/ha.

A strain of *Aspergillus flavus* (F3W4) known to produce aflatoxin was used for inoculations in this experiment (2). The fungus was formulated on autoclaved wheat (*Triticum aestivum* L.) and applied at a rate of 22.4 kg/ha to the four center rows of each plot at growth stage V5 to V6 (4). *Fusarium verticilliodes*, a fungus commonly associated with fumonisin contamination of corn, was allowed to infect naturally. Harpin was applied to the four center rows of selected plots using a CO₂ pressurized backpack sprayer delivering approximately 187 liter/ha at 0.14 MPa. The treatments were: (i) 160 g/ha harpin at V1 to V2 growth stage; (ii) 160 g/ha harpin at V1 to V2 growth stage plus fungal inoculum; (iii) 160 g/ha harpin at V5 to V6 growth stage; (iv) 160 g/ha harpin at V5 to V6 growth stage plus fungal inoculum; (v) untreated control; and (vi) untreated control with fungal inoculum.

The four center rows from each plot were harvested for yield and a 0.5-kg grain sample was collected to determine grain moisture content, grain bulk density, *Aspergillus* colonization and mycotoxin contamination. Yields were adjusted to 15.5% moisture. Data were analyzed using Mix Model Analysis of Variance (PROC MIXED, v. 9.1, SAS Institute Inc., Cary, NC).

Grain Yield

Harpin had no effect on grain yield at either site in both years of the experiment (Table 1). Yields did tend to be greater (*P* ≤ 0.05) on the Beulah fine sandy loam of Site 2 (9607 kg/ha in 2002 and 9444 kg/ha in 2003) than the Dundee silty clay at Site 1 (7659 kg/ha in 2002 and 8286 kg/ha in 2003). However, no improvement in corn yields as a result of harpin application were observed, as has been reported in other crops.

Table 1. Analyses of variance *P* values for harpin treatments on yields, aflatoxin concentrations, fumonisins concentrations, and *Aspergillus flavus* populations for corn grown with furrow irrigation in 2002 and 2003 at Stoneville, MS.

**Mycotoxin Analyses and Fungal Isolation**

After harvesting, all grain samples were analyzed for the presence of aflatoxin and fumonisin. Analyses for the mycotoxins were conducted using ELISA (Vertox, Neogen Crop., Lansing, MI) (3). Data were analyzed using Mixed Model Analysis of Variance (PROC MIXED, v. 9.1, SAS Institute Inc., Cary, NC). Log transformations were conducted on aflatoxin concentrations to facilitate statistical analyses.

No differences in aflatoxin contamination levels were observed among various harpin treatments or when compared with the untreated control (Table 1). Contamination levels ranged from 5.0 ppb to 93.2 ppb with an overall average of 47.3 ppb. Differences ($P \leq 0.01$) in fumonisin contamination were noted between Site 1 (26.7 ppm) and Site 2 (44.3 ppm). No other group of means was significantly different for fumonisin.

**Aspergillus Populations**

*Aspergillus flavus* strains were isolated and their populations calculated from all corn samples and expressed as colony forming units per gram (CFUs/g) similar to procedures of Horn and Doner (15). The treatment × site interaction was statistically significant ($P \leq 0.05$) for CFUs/g (Table 1). No differences in CFUs/g among treatments were observed at Site 1. At Site 2, the CFUs/g for the harpin treatments at V1-V2 were less ($P \leq 0.05$) than the untreated controls (Table 2). The CFUs/g were also less for the harpin treatment at V1-V2 than at V5-V6 in the non-inoculated treatment but did not differ in the inoculated treatment. The CFUs/g at Site 2 were greater than at Site 1 when harpin was not applied. Toxigenic and non-toxigenic strains of *A. flavus* were determined from the plots according to procedures outlined by Abbas et al. (2).

Both toxigenic and non-toxigenic strains of *A. flavus* were isolated from grain treated with harpin indicating it had a similar effect on reducing different populations of the fungus.

Based on our results, harpin as used in this study did not increase corn grain yields. This is different from data reported by Cobum (9). Harpin did reduce fungal colonization at Site 2 when applied at growth stage V1-V2. However, harpin failed to protect corn from fungal colonization at Site 1 and did not reduce mycotoxin contamination at either site. Perhaps harpin has less activity on certain plant species. Ahmad et al. (5) stated that biological activity of harpin may be less in monocots than in dicots, and its involvement in pathogenesis is still uncertain. This is the first report of the effect of harpin on corn colonization by *Aspergillus* and *Fusarium* species and their toxins.
