Abstract. This study was conducted over three crop seasons using ‘Delicious’ (Scarletspar strain) apple trees on MM.111 rootstock. The bioregulators aminooethoxyvinylglycine (AVG) and ethephon (ETH) were applied alone or in combinations at various time intervals before harvest. Fruit response to bioregulators was evaluated at harvest and after storage. AVG applied 4 weeks before first harvest retarded starch loss at harvest, retained greater firmness, and reduced internal ethylene concentration and watercore of fruit at harvest and after both regular and controlled atmosphere storage. AVG did not influence peel color of treated apples. In contrast, ETH enhanced starch hydrolysis, flesh color development (green to more yellow), and soluble solids concentration while reducing titratable acidity levels. ETH had no influence on fruit firmness at harvest, but reduced firmness levels after storage in an inverse relation to the concentration applied. Sensory values for whole apples were not influenced by the combination of both AVG and ETH, but the flesh color of treated apples was more green. AVG in all instances tended to reduce the sensory scores for apples and apple juice. In contrast, ETH enhanced starch hydrolysis, flesh color development (green to more yellow), and soluble solids concentration while reducing titratable acidity levels. ETH had no influence on fruit firmness at harvest, but reduced firmness levels after storage in an inverse relationship to the concentration applied. Sensory values for whole apples were not influenced by ETH treatment, but ETH improved sensory preference for apple juice, particularly at early harvest. Applying AVG before ETH enhanced soluble solids and sensory scores for both fruit and juice. Treating with AVG followed by ETH at 150 mg-L⁻¹ permitted the maintenance of satisfactory firmness values (>53.4 N) after long-term storage along with better quality and sensory perceptions. Using specific combinations of both AVG and ETH permitted ETH-mediated improvements in objective and perceived fruit quality to be obtained without the losses in flesh firmness and storability due to uncontrolled ethylene evolution and ripening typically observed when ETH is applied alone preharvest.

Bioregulators can influence many important physiological processes in tree fruits when applied before harvest. Two bioregulators, aminoethoxyvinylglycine (AVG) (ReTain; Valent BioSciences, Walnut Creek, Calif.) and ethephon (ETH) (Ethrel, Bayer Crop Science, Research Triangle Park, N.C.) have been used to manipulate both tree and fruit physiological behavior (Looney, 2004). Control of vegetative growth and regulation of flowering (Elfving and Cline, 1990; Elfving et al., 2003), preharvest drop (Greene et al., 2000; Stover et al., 2003), fruit maturity (Byers, 1997; Greene, 2002; Layne et al., 2002; Stover et al., 2003; Wang and Dilley, 2001), fruit size, fruit shape, fruit color, fruit firmness, and postharvest quality (Andrews, 2001; Beaudry and Jayanty, 2003; Drake et al., 2002, 2003, 2005; Halder-Doll and Bangerth, 1987; Larrigaudiere, 1996; Watkins and Rosenberger, 1999; Wang and Dilley, 2001; Williams, 1980) have all been manipulated with the use of bioregulators. While many reports document effects on fruit quality, little information on bioregulator effects on sensory perception of fruit quality by consumers is available. One study suggests that a key factor that stimulates sales of apples is flavor (Washington Apple Commission, 2002).

Ethylene is thought to be the naturally occurring hormone that triggers fruit ripening (Blanpied, 1972). AVG inhibits ethylene biosynthesis by the fruit, thereby retarding the ripening process (Bangerth, 1978). ETH releases ethylene upon uptake by plant tissues (Yang, 1969); applying ETH to apple trees shortly before harvest can induce ethylene biosynthesis in and early ripening of fruit (Edgerton and Blanpied, 1968). However, preharvest ETH treatment also stimulates the climacteric behavior of the fruit, thereby reducing its capacity for long-term storage. Could the ethylene biosynthesis-inhibiting properties of AVG be exploited to allow brief bursts of ethylene from preharvest exogenous applications of ETH to temporarily stimulate ripening processes in apples without inducing the uncontrolled biosynthesis of ethylene in apple fruit and the accompanying loss of storability and quality? Combinations of AVG and ETH have been shown to permit better fruit color development in ‘McIntosh’ apple while controlling fruit ripening and maintaining fruit storability (Wang and Dilley, 2001).

The objectives of this project were 1) to evaluate the effects of AVG and ETH applied either separately or sequential trees on objective measures of fruit quality, 2) to document any effects of these bioregulators on human perceptions of sensory qualities of fresh apples or apple juice, and 3) to determine whether any bioregulator-induced improvements in sensory perception could be obtained while minimizing negative effects on storability or the incidence of fruit disorders.

Materials and Methods

This study was conducted over three crop seasons using mature ‘Delicious’ (Scarletspar strain) apple trees on MM.111 rootstock. Trees were located in a commercial orchard in East Wenatchee, Wash., and were planted in 1979 at a spacing of 3.3 x 6.6 m.

Trial 1 (2000). Applications of AVG were made to single-tree replications in five randomized complete blocks to runoff using a hydraulic hand-gun sprayer. Treatments were sprayed at 4 weeks before first (commercial) harvest (4 WBH) with 125 mg-L⁻¹ AVG supplemented with 0.1% v/v SilWet surfactant (Kalo, Overland Park, Kan.). Control trees were not sprayed with either bioregulator or surfactant.
Trial 2 (2000). Applications of ETH were made to single-tree replications in six randomized complete blocks to runoff using a hydraulic hand-gun sprayer. Trees were sprayed at either 1 or 2 weeks before first (commercial) harvest (WBH) with either 150 or 300 mg L^-1 ETH. All sprays were supplemented with 0.1% v/v Regulaid surfactant (Kalo). Control trees were not sprayed with either bioregulator or surfactant.

Trial 3 (2001). Five randomized complete blocks containing six double-tree replications each were selected from another part of the orchard that had not been previously treated with either AVG or ETH. Five double-tree replications per block (ten trees per block) were sprayed 4 WBH with 125 mg L^-1 AVG plus 0.1% v/v Sylgard 309 organosilicone surfactant (Wilbur-Ellis, Fresno, Calif.) to runoff using a hydraulic hand-gun sprayer. The sixth double-tree replication in each block served as an unsprayed control. Four double-tree replications previously treated with AVG were individually sprayed to runoff using a hydraulic hand-gun sprayer with one of the following combinations of ETH and timing: ETH 150 mg L^-1 at either 2 WBH or 1 WBH or ETH 300 mg L^-1 at either 2 WBH or 1 WBH. All ETH sprays were supplemented with 0.1% v/v Regulaid surfactant. Control trees were not sprayed with either bioregulator or surfactant.

Trial 4 (2002). Seven randomized complete blocks containing six four-tree replications each were selected from a part of the orchard that had not been previously treated with either AVG or ETH. Three four-tree replications per block (twelve trees per block) were sprayed 4 WBH with 125 mg L^-1 AVG plus 0.1% v/v Sylgard 309 organosilicone surfactant to runoff using a hydraulic hand-gun sprayer. One four-tree replication in each block served as an unsprayed control. The other two four-tree replications previously treated with AVG were individually sprayed to runoff with either ETH 150 mg L^-1 at 2 WBH or with ETH 75 mg L^-1 at 2 WBH and again at 1 WBH to runoff. The remaining two untreated four-tree replications were treated with ETH at either 75 or 150 mg L^-1 as described above. All ETH sprays were supplemented with 0.1% v/v Regulaid surfactant. Control trees were not sprayed with either bioregulator or surfactant.

Apples were harvested on two dates each year of the study corresponding to first commercial harvest and commercial harvest + 2 weeks (18 Sept. and 2 Oct., 2000, Trial 2; 20 Sept. and 4 Oct., 2000, Trial 1; 10 Sept. and 24 Sept., 2001, Trial 3; 23 Sept. and 7 Oct., 2002, Trial 4). On each harvest date, 90 apples were harvested at random from each replication. Each sample consisted of 10 apples from different branches of a tree. Fruit was harvested at the commercial maturity stage, washed, surface dried, sliced and juiced using a juicer (model 4000; Omega Products, Inc., Harbison, S.C.) at ambient temperature. Juice was centrifuged in an IEC (Centra-7; International Equipment Co., Needham Heights, Mass.) at 5230 x g and then filtered through an odor-free coffee filter to remove all insoluble solids. The juice from each group within a treatment was combined and stored at 5.6 °C for immediate flavor panel evaluation.

Sensory analysis: Juice. Sensory testing was conducted on apple juice samples in a laboratory environment by a panel of 25 judges that had previously been trained in apple juice flavor attributes (Tree Top, Inc., Selah, Wash.). Each panelist received two samples that were color coded to indicate a control and a treatment sample. Panelists were not aware of the relationship of color coding to treatment and were instructed before the evaluation on the proper method for filling out the ballot describing their choices. Each evaluation session was limited to two groups of two samples (four juice samples in total).

The ballot consisted of three parts. Each panelist was asked to rate the intensity of the apple flavor for each sample using a 9-point scale, where 1 = indicated that the apple flavor was too weak, 5 = that the apple flavor was just right, and 9 = that the flavor was too strong. Finally, each panelist was asked to rate their overall degree of liking of each juice sample using a 9-point scale, where 1 = dislike extremely, 5 = neither like nor dislike, and 9 = like extremely.

Sensory analysis of whole apples. Consumers (N > 100) were recruited at the North Carolina State University (NCSU) Sensory Service Center, Raleigh, N.C., before each taste test. Consumers evaluated freshly cut and cored apple slices for overall liking, flavor and texture acceptability using a 9-point hedonic scale anchored on the left with “dislike extremely” and on the right with “like extremely” (Meilgaard et al., 1999). Apples were presented in a randomized, balanced order of presentation on paper plates with a random three-digit code designating each treatment on each plate. Before testing, each consumer panelist filled out an informed consent form for NCSU Human Subjects Approval and a brief questionnaire on apple consumption habits.

Consumer taste-panel demographics were similar for the various harvests each year. Consumers were fairly evenly split between genders (58% female, 42% male); 55% were between 19 and 29 years old and 45% were between 30 and 55 years old. All consumer participants indicated a liking for apples, but frequency of apple consumption varied widely. Forty percent consumed apples seasonally or a least once per month, while 35% consumed apples a few times per week. Consumers were also asked to list the apple cultivars they consumed most often. ‘Delicious’ (62%), ‘Fuji’ (47%), ‘Granny Smith’ (50%), ‘Golden Delicious’ (51%), ‘Gala’ (42%), and ‘McIntosh’ (23%) were the most commonly cited cultivars. Of consumer panelists, 85% indicated that flavor was a critical factor in apple choice and purchase; 72% indicated texture and 51% indicated color as critical factor in apple choice and purchase.

Results and Discussion

AVG retarded flesh firmness and starch loss independent of harvest date but did not affect SSC, TA, or SSC to TA ratio (Table 1). Delaying harvest by 2 weeks resulted in reduced flesh firmness and TA and increased starch hydrolysis. ETH treatments had no effect on fruit firmness but increased SSC to TA ratio (300 mg L^-1 treatment only) and starch hydrolysis while having no effect on TA levels. A 2-week harvest delay again resulted in reduced firmness and increased starch hy-
drolysis but had no effect on SSC, TA or SSC to TA ratio. Fruit weight was not affected by bioregulator treatments but was greater on the second harvest date (data not shown). The effects of delaying harvest produced similar responses in fruit quality parameters in both Trials 1 and 2.

AVG treatment resulted in reduced peel red color development that would not be visible to the average consumer due to the significant but small corresponding change in hue value (Table 2). A change in hue value of one or more unit is required to visually identify color differences (Hunter and Harold, 1987). AVG treatment reduced color development in other less highly colored apple cultivars (Greene, 2002; Wang and Dilley, 2001). Delaying harvest by 2 weeks in this study resulted in small changes in L values but no observable change in peel hue value. In contrast, AVG treatment produced apple flesh color that was more green (higher hue value) than nontreated apples. Greener flesh color could be related to slower maturity, which was indicated by the reduction in starch hydrolysis (Table 1). ETH did not influence the peel color of apples regardless of the amount of ETH applied or time of application. This result did not agree with the increased red color observations of Larrigaudiere et al. (1996) and Stover et al. (2003), but those studies were not conducted with the Scarletspur strain of 'Delicious', which is characterized by intense, early red color development in the peel. However, ETH produced a darker flesh color (lower L values), with less green and more yellow. The lower hue values associated with ETH application indicated a flesh color typical of more mature fruit. These changes in flesh color were very evident regardless of the amount of ETH applied or time of application. The higher ETH concentration tended to have more influence on flesh color than the lower (150 mg L⁻¹), particularly when applied at 1 WBH, which allowed less time for the ETH effect to be developed.

After both RA (60 d) and CA (150 d) storage, AVG-treated fruit were firmer than nontreated apples, regardless of harvest date (Table 2). After both 60 d RA and 150 d CA storage, all fruit met or exceeded the minimum Washington State grade standard for firmness of 54 N (Washington Agriculture Code, 1990). However, AVG-treated fruit were substantially firmer than untreated fruit, indicating that AVG treatment resulted in better tissue texture conservation under RA and CA storage conditions.

Table 1. Effects of aminoethoxyvinylglycine (AVG) or ethephon (ETH) applied preharvest on objective quality attributes of 'Delicious' (Scarletspur strain) apples at harvest (Trials 1 and 2, 2000).

HortScience Vol. 40(7) December 2005
of concentration, time of application, or harvest date, met the minimum Washington State grade standard for firmness, although the ETH 300 (2 WBH) treatment just barely met the standard (Table 2). After 150 d of CA storage, control fruit were firmer than any ETH treatment, and again all treatments met the minimum firmness standard, with the high ETH concentration fruit just exceeding that value. Fruit from the later harvest date were less firm after both 60 and 150 d of storage, but all fruit met the minimum firmness standard.

Applications of ETH alone to apples at 150 or 300 mg L⁻¹ at 1 or 2 WBH increased the preference, intensity and liking sensory scores of apple juice on both harvest dates over juice from untreated fruit (Table 3, Trial 2, 2000). Apple juice flavor intensity scores for the ETH treatments groups were closer to the 5.0 score of "just right" while the control group flavor intensity score was more toward "weak". At the second harvest the improvement in quality perception from preharvest ETH applications when compared to controls was not as conspicuous. Apple juice flavor intensity from the ETH 2 WBH group was near the 5.0 scale of "just right" while the juice from the ETH 1 WBH group and the control group were toward the "weak" intensity score. Liking scores followed a similar pattern in which the 2 WBH group apple juice exhibited higher scores than the 1 WBH group. Because of better flavor intensity and liking scores, apple juice from all the second harvest treatment groups except the 300 mg L⁻¹ ETH (1 WBH) were preferred over the juice from the control group. At the second harvest (II), control fruit had matured enough that only apples treated with 300 mg L⁻¹ ETH at 2 WBH produced juice with preference, intensity and liking scores superior to nontreated fruit.

Apple juice samples from apples treated with AVG alone were similar in preference, intensity and liking to juice from control fruit at the first harvest (Table 3, Trial 3, 2001). Juice from apples treated with ETH in addition to AVG was preferred to juice made from control fruit, except when 300 mg L⁻¹ ETH was applied 1 WBH; in this instance there was no difference in preference. Apple juice flavor intensity scores were similar among bioregulator treatments and control fruit. Apple juice from apples treated with a combination of AVG and ETH (150 or 300 mg L⁻¹, 2 WBH) was scored higher for liking when compared to juice from control fruit. All other treatments received similar scores to control fruit juice for liking.

At the second harvest, juice from control fruit was preferred to juice made from apples treated with AVG alone (Table 3, Trial 3, 2001). When ETH was applied in conjunction with AVG, preference scores for juice were superior to juice from control fruit, except again in the instance where ETH was applied at 300 mg L⁻¹ 1 WBH. By the second harvest, control fruit had matured enough that juice scores for apple flavor intensity were similar to all AVG + ETH treatments, although AVG alone had a lower intensity score than three of four AVG + ETH treatments. When AVG and ETH were used sequentially, juice liking scores from some of the treatments were preferred at the first harvest, but no differences in juice liking were detected at the second harvest.

In the final year of the study, apple juice from fruit treated with AVG was preferred when compared to juice from control fruit, but only at the first harvest (Table 3, Trial 4, 2002). At the second harvest no preference was indicated between juice from AVG treated or control fruit.

*AVG applied 4 weeks before first harvest.
apples. At the first harvest, juice from treated
ETH fruit was preferred, except when ETH
was applied at 150 mg L\(^{-1}\) (2 WBH). In this
instance apple intensity was also reduced and
no preference between juice from control fruit
or juice from treated fruit was indicated. At all
other rates and application times, apple flavor
intensity was enhanced by the use of ETH.
Panel scores indicated no difference in liking
for juice from apples at the first harvest, regard-
less of the use of AVG or ETH. At the second
harvest, no preference was evident between
juice from treated (AVG alone or AVG + 75
mg L\(^{-1}\) 2 + 1 WBH) or control fruit. However,
juice from control fruit was preferred over juice
from apples treated with AVG + 150 mg L\(^{-1}\)
ETH 2 WBH or 75 mg L\(^{-1}\) ETH 2 + 1 WBH and
150 mg L\(^{-1}\) ETH 1 WBH. Apple juice intensity
scores were also reduced for juice from these
trials, particularly for juice from apples
-treated with AVG + 150 mg L\(^{-1}\) ETH 2 WBH
before harvest. Panelists indicated the juice
to be weak in flavor intensity. At the second
harvest, liking scores were similar between
treatments except for the juice score from
apples treated with AVG + 150 mg L\(^{-1}\)
ETH 2 WBH, which was reduced when compared
to juice from all other treatments.
In 2001, there was little difference in fruit
firmness at harvest among treatments (Table 4).
Application of ETH following AVG did not
reduce firmness at harvest but did increase SSC
and SSC to TA ratio. Bioregulator treatments
did not affect TA at harvest. Delaying harvest
due to 2 weeks resulted in decreased flesh
firmness and TA and increased SSC and SSC to TA
ratio. Apples treated with AVG alone displayed
a reduced overall sensory acceptance score when
compared to control fruit or fruit treated with
a combination of AVG and ETH (Table 4). Only
apples with AVG and 300 mg L\(^{-1}\) ETH applied
2 WBH were considered superior in overall
acceptance to control fruit, while apples treated
with other combinations of AVG and ETH were
rated as similar to control fruit. Sensory flavor
scores for apples treated with AVG alone were
similar to flavor scores of control apples, but
lower than flavor scores for fruit treated with
a combination of AVG and ETH. The sensory
flavor score for apples treated with AVG
plus 300 mg L\(^{-1}\) ETH 2 WBH was superior
to control apples. As expected, fruit texture
scores were similar between control apples
and treated apples either with AVG alone or
in combination with ETH. Previous research
has indicated that AVG-treated apples maintain
firmness better than nontreated fruit (Beaudry
and Jayanty, 2003; Wang and Dilley, 2001).
In the present study the whole-apple sensory panel
findings reflected the virtual absence of differ-
ences in the objective firmness data recorded for
these fruit. Firmness loss in apples due to
ETH application has been reported in other
trials (Drake et al., 2002). In this case AVG
followed by ETH did not result in significant
sensory textural deterioration at harvest. Delay
of harvest permitted additional fruit maturation
and resulted in an increase in overall sensory
acceptance, flavor and texture scores.
In 2002, the double application of ETH (75
mg L\(^{-1}\)) resulted in a reduction in flesh firmness
at harvest; all other treatments had no effect on
flesh firmness (Table 5). AVG alone reduced
SSC at harvest while ETH increased SSC. ETH
reversed the effect of previous AVG on SSC
and SSC to TA ratio at harvest; SSC and SSC
to TA ratio values were as high or as higher
than the control. TA at harvest was unaffected
by bioregulator treatments. Delaying harvest
due to 2 weeks resulted in reduced flesh
firmness and higher SSC and SSC to TA ratio values,
while having no detectable effect on TA.
In a second year of consumer panel evaluation
of whole apples, fruit treated with AVG
were similar to control apples in overall
acceptance, flavor and texture scores (Table 5).
Overall sensory acceptance and flavor were
only enhanced with the use of AVG + the
highest ETH rate used (150 mg L\(^{-1}\) ETH 2
WBH). In most instances, including ETH after
AVG enhanced overall sensory acceptance and
flavor when compared to apples treated with
AVG alone. Delay of harvest again resulted in
increased overall sensory acceptance and
flavor scores, but did not change sensory
texture scores. In the demographics survey
before sensory analysis of whole apples, 85%
of consumers indicated that flavor was a critical
factor in apple choice and purchase; 72% indicated
texture and 51% indicated that color was
a critical factor in apple choice and purchase.
This emphasis on apple flavor by consumers
has also been reported in another study (Wash-
ington Apple Commission, 2002).
During the second year of this study, AVG
alone or a combination of AVG and ETH along
with harvest time had a strong influence on
starch hydrolysis and firmness after RA and
CA storage (Table 6). At the first harvest, starch
content was unaltered by AVG alone. Follow-
ing AVG with ETH had no effect on starch
hydrolysis by the first harvest date except for a
slight increase when ETH was applied at the
higher concentration the longest interval before
harvest (300 mg L\(^{-1}\), 2 WBH). By the second
harvest, fruit treated with AVG displayed less
starch hydrolysis than control fruit. Adding
ETH as a post-AVG treatment stimulated starch
hydrolysis so that starch levels were similar
to control fruit.
After 60 d of RA storage, fruit treated
with AVG alone were firmer than fruit treated
with AVG + ETH regardless of the amount of
ETH or time of application, especially at the
first harvest (Table 6). By the second harvest,
AVG treated fruit were still firmer than fruit
-treated with AVG + 300 mg L\(^{-1}\) ETH, regard-
less of time of application, but equivalent in
firmness to fruit treated with AVG plus ETH at
the lower concentration. In all cases, treatment
with AVG resulted in firmer fruit than controls,
with or without ETH. In CA storage (120 d),
fruit treated with AVG alone were only firmer
than fruit treated with AVG + 300 mg L\(^{-1}\) ETH
at (2 WBH). Again, nearly all AVG treatments
maintained flesh firmness better than control
fruit. Regardless of treatment, firmness of all
fruit (60 RA, 120 CA) met or exceeded
Washington State grade standards. After 180
d of CA storage, AVG alone and AVG + ETH
treated apples were similar in firmness (66 to
68 N) and firmer (59.8 N) than control apples
when harvested early. If harvested was delayed
2 weeks, only AVG and AVG + ETH at 150
mg L\(^{-1}\) met or exceeded Washington State
grade standards (53.4 N) for firmness after 180
d of CA storage. Late-harvested control fruit
and any fruit treated with AVG + ETH at 300
mg L\(^{-1}\) failed to meet grade standards.
AVG application did not influence the

were harvested early. By the second harvest, peel color of 'Delicious' (Scarletspar strain) apples after 60 d of RA storage or 120 d of CA storage, regardless of harvest time (Table 7). After 180 d of CA storage, AVG treated fruit displayed redder (lower hue) peel color than control fruit from both harvest, but only at this storage duration. Use of AVG + ETH (150 or 300 mg L⁻¹) produced darker (lower L values), redder (lower hue value) apples than controls at all storage times, but only when apples were harvested early. By the second harvest, no bioregulator treatment affected peel color after 180 d CA storage.

AVG treatment reduced IEC compared to control fruit at harvest and after all storage times, regardless of fruit harvest date (Table 8). Application of ETH following AVG treatment did not overcome the AVG-based control over fruit ethylene production, even after 180 d in CA. IEC was higher for fruit harvested on the second harvest date, but the relationship of fruit IEC to treatments remained the same. At both harvests, the amount of watercore present was similar regardless of the amount of ETH applied. After 60 d of RA storage, apples treated with AVG displayed significantly less watercore than apples treated with AVG + ETH, regardless of the amount of ETH applied. AVG + ETH treated apples displayed watercore at a similar level as control apples. These differences in watercore were also evident after 120 d of CA storage. After 180 d of CA storage, apples treated with AVG + ETH at 150 mg L⁻¹ (1 WBH) showed more watercore than all other treatments, which were the same.

Conclusions

AVG and ETH are both tools used to manipulate fruit maturity and quality; AVG delays the changes associated with maturity and ripening while ETH accelerates those changes. In this study, AVG delayed fruit maturity and flesh firmness loss, but reduced flavor. ETH reduced flesh firmness but aided flavor development. Because following AVG-treated fruit with ETH before harvest did not stimulate uncontrolled fruit ethylene evolution, combination treatments of AVG and ETH produced fruit with improved flavor and texture retention even after short or long-term storage. Using AVG and ETH overcame the disadvantages of either product when used alone. Fruit quality was best at harvest and after storage with a combination of both AVG and ETH.

Fruit continue to mature and ripen until harvested. In this study, quality attributes (objective and subjective) were superior for all treatments at harvest I (commercial) versus harvest II (2-week delay). Earlier-harvested fruit showed lower water core, better firmness and better flavor, liking and preference scores.

This harvest-date effect on fruit quality continued through both RA and CA storage. AVG treatment alone produced apples with optimum objectively measured characteristics but not the best flavor quality in all 3 years. ETH applied at 300 mg L⁻¹ reduced subjective perception quality scores, particularly for texture; this concentration was probably too high for this cultivar. The results of this study suggest that preharvest AVG followed by ETH at 2 WBH applied to fruit harvested at the commercial harvest date may be the best approach for optimizing all quality attributes, both objective and subjective, while maintaining long-term storability.
