Five strains of simmondsin-degrading, lactic-acid-producing bacteria were isolated from fermented jojoba meal. These isolates were facultatively anaerobic, Gram-positive, non-motile, non-spore-forming, homofermentative, rod-shaped organisms. They grew singly and in short chains, produced lactic acid but no gas from glucose, and did not exhibit catalase activity. Growth occurred at 15 and 45 °C. All strains fermented cellobiose, D-fructose, D-galactose, D-glucose, lactose, maltose, D-mannitol, D-mannose, melibiose, D-ribose, salicin, D-sorbitol, sucrose and trehalose. Some strains fermented L-(-)-arabinose and L-rhamnose. D-Xylose was not fermented and starch was not hydrolysed. The mean G+C content of the DNA was 48 mol%. Phylogenetic analyses of 16S rDNA established that the isolates were members of the genus *Lactobacillus*. DNA reassociation of 45% or less was obtained between the new isolates and the reference strains of species with G+C contents of about 48 mol%. The isolates were differentiated from other homofermentative *Lactobacillus* spp. on the basis of 16S rDNA sequence divergence, DNA relatedness, stereoisomerism of the lactic acid produced, growth temperature and carbohydrate fermentation. The data support the conclusion that these organisms represent strains of a new species, for which the name *Lactobacillus arizonensis* is proposed. The type strain of *L. arizonensis* is NRRL B-14768 (= DSM 13273).

**Keywords**: new species, taxonomy, simmondsin degrader, jojoba, *Lactobacillus arizonensis*

---

**INTRODUCTION**

Jojoba (*Simmondsia chinensis*) is an important commercial seed crop grown in the desert southwestern United States. Up to 60% of the seed weight consists of a unique oil that is used in the cosmetic and skin care industry. After hexane extraction of the oil, the remaining meal contains 25–30 % crude protein, is high in fibre and could be a valuable cattle feed supplement. However, this meal is not currently fed to animals because it contains 5-demethyl simmondsin, 4,5-didemethylsimmondsin, simmondsin and simmondsin 2'-ferulate (Elliger *et al.*, 1973, 1974a, b; Verbiscar & Banigan, 1978). These substances are cyanogenic toxins that have been implicated in weight loss of ruminants (Manos *et al.*, 1986) and in the death of mice (Weber *et al.*, 1983).

Studies by Verbiscar *et al.* (1981) indicated that *Lactobacillus* spp. attacked simmondsin in autoclaved meal but not when used as a sole carbon source in culture media. As the result of a screening effort, Abbott *et al.* (1990) obtained isolates of *Stenotrophomonas maltophilia*, *Flavobacterium aurantiacum* and *Fusarium moniliforme* that attacked simmondsin when used as a sole carbon source; however, only *F. moniliforme* degraded simmondsin effectively in the meal. Microbiological evaluation of large batches of meal inoculated with *F. moniliforme* and incubated out of doors revealed the involvement of bacteria as well as fungi in the simmondsin-degrading process.

The purpose of this study was to identify the simmondsin-degrading bacteria isolated from fermented jojoba meal. The results indicate that the simmondsin-de-
grading isolates represent strains of a new Lactobacillus species.

METHODS

Bacterial strains. The strains were isolated from sterile jojoba meal that had been inoculated with F. moniliforme and fermented for 20 d in the open air of Hyden Valley Desert in Arizona. One gram samples of meal were suspended in 100 ml 0.85 % (w/v) sterile saline and 0.2 ml serial dilutions were spread on modified Rogosa SL agar in which the dextrose, l- (+)-arabinose and sucrose was replaced by 0.5 % (w/v) simmondsin. Incubation was at 37 °C in an anaerobic jar having a H₂ plus CO₂ environment generated with a BBL Gas Pak (Becton Dickinson Microbiology Systems). Small, white, opaque, raised colonies appearing after 48 h were streaked onto MRS agar for purification.

The reference strains used in the DNA reassociation studies were Lactobacillus amyrophyllus NRRL B-4437, Lactobacillus coryniformis NRRL B-4391, Lactobacillus plantarum NRRL B-4496, Lactobacillus paracasei subsp. paracasei NRRL B-4560, Lactobacillus rhamnosus NRRL B-176, Lactobacillus casei subsp. casei NRRL B-1922, Lactobacillus delbrueckii subsp. delbrueckii NRRL B-763 and Lactobacillus pentosus NRRL B-473. These strains are maintained at the Agricultural Research Service Culture Collection at the National Center for Agricultural Utilization Research, Peoria, IL, USA.

Characterization tests. Carbohydrate fermentation tests were conducted in modified MRS medium (Kandler & Weiss, 1986) with 0.0016 % (w/v) bromocresol purple as an indicator. Inverted Durham tubes were placed in the broth tubes to detect gas production. Starch utilization was determined by growing micro-organisms on MRS agar plates containing 0.5 % (w/v) soluble starch. The hydrolysis of starch was detected by flooding the plates with 1.0 ml iodine solution (0.2 g I₂ and 2.0 g KI in 100 ml distilled water). To determine growth at different temperatures (10, 15, 20, 25, 30, 35, 40, 45 and 50 °C), preincubated sterile medium in 15 x 150 mm screw-capped test tubes was inoculated and incubated in a Control Environment Incubator (New Brunswick Scientific).

Inocula for the characterization tests were prepared from cultures grown for 24 h at 37 °C in MRS broth. Cells were harvested by centrifugation at 4 °C. washed in sterile 0.85 % saline and resuspended in sterile saline solution. One-tenth millilitre aliquots of inoculum were added to each test tube containing 5 ml medium. All tests were run in duplicate and incubated at 37 °C in an anaerobic jar with the screw caps loosened. readings were taken at 1, 5 and 10 d.

Simmondsin degradation was determined by growing the isolates in deep liver medium (McCung & McCoy, 1934), which was modified to contain 5 g l⁻¹ simmondsin instead of glucose as the carbohydrate source. Samples of the fermented broth were filtered through a 0.45 μm pore size Millipore membrane and frozen. Ten microlitre aliquots of the sample were injected into a HPLC system consisting of an SP8800 ternary pump (Spectra-Physics), ISCO V° absorbance detector (ISco), Econosphere C-18 3 μm 100 x 4.6 mm i.d. column (Alltech) and a central ModComp 32/85 computer system (Modular Computer Systems). A linear 5-100 % aqueous methanol gradient over 10 min at 0.75 ml min⁻¹ was used for all determinations. Column effluents were monitored at 220 nm. Analysis time per sample, including re-equilibration, was typically 20 min. Peak areas in samples of fermentation media with no toxin (i.e. media blanks) were subtracted from sample peak areas. Toxin peak area in fermented samples (after media subtraction) was divided by toxin peak area in unfermented samples to determine the fraction of toxin that was not degraded. The retention time of simmondsin was 8.9 min.

Analyses of metabolic acid products. The concentration of lactic acid and other organic acids was measured by HPLC of cell-free supernatant of cultures incubated for 1 and 6 d in deep liver medium. The organic acids and other medium components were resolved on a HPX-87H column (Bio-Rad) and monitored with a refractive index detector (Shimizu et al., 1989).

To determine the stereoisomerism of the lactic acid products, cultures were grown for 48 h at 37 °C in 11 MRS broth modified to contain 1 % (w/v) glucose. To prepare samples for assay, 15 ml culture liquor was centrifuged at 10000 g for 15 min at 4 °C, and the resulting supernatant was deproteinized by titration with concentrated NaOH to pH 7.6 in the presence of 5 % (w/v) ZnSO4. The precipitate was removed by centrifugation at 4 °C and the supernatant was analysed. Beef heart l- (+)-lactate dehydrogenase (EC 1.1.1.27) and Lactobacillus leichmannii d- (−)-lactate dehydrogenase (EC 1.1.1.28) were used for assessing the stereoisomerism of the lactic acid produced by the simmondsin-degrading isolates. Enzymes were purchased from Boehringer Mannheim. The method used was that of Latorre-Guzman et al. (1977). The assay mixture consisted of 0.1 ml (50 μg) enzyme solution, 2.0 ml glycine/hydrizine sulphate buffer [7.5 % (w/v) glycine, 5.2 % (w/v) hydrazine sulphate, 0.2 % (w/v) sodium EDTA and 0.2 % (w/v) NaOH; pH 9.5], 0.1 ml 56 mM NAD solution, 0.1 ml of appropriately diluted sample and 0.7 ml distilled water. Uninoculated broths with and without l- (+) - and d- (−)-lithium lactate were used as controls. The above-mentioned enzymes showed specificity for their respective substrates. Substrate utilization, indicated by NAD reduction, was monitored at 340 nm in a UV-VIS Thermal Analyzer System (Giford Systems).

DNA base composition and reassociation. DNA was extracted and purified by a modification of the method of Marmur (1961). The modification involved the use of hydroxyapatite (Bio-Gel HTP; Bio-Rad) chromatography (Markov & Ivanov, 1974) to produce highly purified DNA preparations. The purity and quality of each DNA preparation were checked by monitoring the absorbance ratio at 260/280 nm (1.8-1.9) and at 260/230 nm (2.0-2.3) (according to Marmur, 1961) and by the melting curves, which showed hyperchromicity values from 38 to 40 % (Mandel & Marmur, 1968).

The G+C content of the DNA was estimated by the buoyant density method (Schildkraut et al., 1962). Buoyant density of the DNA was measured by CsCl density gradient centrifugation in a Beckman Instrument model E ultracentrifuge. 'Micrococcus lysodeikticus' DNA served as an internal standard.

DNA reassociation values were obtained by a spectroscopic method described previously (Nakamura & Swezy, 1983). Percentage relatedness values were calculated by the equation of DeLev et al. (1970). All DNA reassociation determinations were repeated twice.

16S rDNA sequencing. A 16S rDNA fragment of strain NRRL B-14768 that corresponds to positions 9-1510 of
Lactobacillus arizonensis sp. nov.

RESULTS

Morphology and physiology

The five simmondsin-degrading isolates (NRRL B-14768T, NRRL B-14769, NRRL B-14770, NRRL B-14771 and NRRL B-14772) were Gram-positive, non-motile rods that occurred singly or in short chains. Phase-contrast microscopic examinations of broth or agar cultures grown aerobically or anaerobically revealed no spores after 2 weeks incubation at 37°C. Granules were noted in some microscopically observed Gram-stained cells. Mean cell measurements were 1 x 4-5 μm. Colonies on MRS agar were white, smooth, circular, convex and opaque. The isolates grew at both 15 and 45°C but not at 10 or 50°C, and optimally at 35–40°C (based on visual inspection). They were catalase-negative and failed to hydrolyse starch. The isolates grew anaerobically and at initial pH values that ranged from 4.5 to 8.0; the pH was adjusted with 1 and 5 M HCl or NaOH. Growth was not detected in MRS medium that lacked a metabolizable sugar. All isolates degraded approximately 90% of the simmondsin after 6 d. By comparison, 0–70% degradation was recorded from the other Lactobacillus reference strains examined (Table 1). The fermentation pattern of the carbohydrates listed in Table 1 was useful for differentiating the isolates from the recognized species. Mannitol, melibiose, raffinose, d-ribose, D-ribose, L-Rhamnose, D-Xylose, and L-(-)-Arabinose were fermented to separate products. The other carbohydrates were not fermented.
Fig. 1. Phylogenetic tree showing the position of Lactobacillus arizonensis NRRL B-14768T among selected bacteria belonging to the Lactobacillaceae. The tree, which is rooted by using Bacillus subtilis as the outgroup, was generated by the neighbour-joining method. Bootstrap values based on 500 replications are given at the nodes. Trees generated by the neighbour-joining method and by maximum-parsimony analysis had similar topologies. GenBank accession numbers are given in parentheses. The bar represents 10% sequence divergence.

Sorbitol and trehalose were fermented by all the isolates: L-arabinose and L-rhamnose were fermented only by NRRL B-14768T and NRRL B-14769. Starch and D-xylose were not fermented. Other sugars fermented (not shown) were cellobiose, D-fructose, D-galactose, D-glucose (no gas produced), lactose, maltose, D-mannose, salicin and sucrose.

Analysis revealed that the isolates apparently produced only lactic acid (0.046 mol) from glucose (0.028 mol) in 6 d. and therefore the organisms are homofermentative. Theoretically, homofermentative conversion should yield 2 mol lactic acid for each mol glucose consumed. Therefore, the isolates converted approximately 80% of the glucose to lactic acid. Under optimum conditions L. delbrueckii (Schöp­meyer, 1954) fermentations have given 95% yields. Determination with specific enzymes demonstrated that both D-(-)- and L-(+)-lactic acids were produced.

16S rDNA sequence

Similarity values (not shown) of 95 % established that NRRL B-14768^ was most closely related to members of the genus Lactobacillus. Values of 80–87 % suggested a more distant relationship between NRRL B-14768^ and the genus Carnobacterium. Data searches using the BLAST system (Altschul et al., 1990) corroborated the positioning of NRRL B-14768^ within the genus Lactobacillus, the closest relatives being L. plantarum and L. pentosus. In a neighbour-joining tree (Fig. 1) based on sequences obtained in this study and from the GenBank database, NRRL B-14768^ is positioned in the L. casei/Pediococcus cluster (Collins et al., 1991). Thus, the data demonstrate that NRRL B-14768^ clearly belongs to the genus Lactobacillus and is closely related to L. plantarum and L. pentosus. This relationship was supported by the bootstrap analyses at a confidence level of 100 %.

DNA base composition and reassociation

The buoyant densities of the DNAs for the isolates ranged from 1.7069 to 1.7073 g ml^-1, which corresponds to G + C contents of 47.8–48.3 mol %. These G + C values are within the range reported for Lactobacillus (Kandler & Weiss, 1986). Table 2 shows that DNA relatedness ranging from 5 to 45 % was obtained between the simmondsin-degrading strains and homofermentative Lactobacillus species having G + C values of 45–50 mol %. DNA relatedness of 70–100 % was measured among all simmondsin-degrading strains. Studies have shown that microorganisms with DNA relatedness of 70 % or higher belong to the same species (Johnson, 1973).

DISCUSSION

The simmondsin-degrading strains were isolated from fermenting jojoba meal on modified acetate agar (Rogosa et al., 1951), a selective medium for Lactobacillus species. These isolates were homofermentative, facultative, anaerobic or microaerophilic. Gram-positive, non-motile, non-spore-forming, rod-shaped cells that grew singly or in short chains and did not produce gas from glucose, were catalase-negative, and produced substantial amounts of lactic acid. These characteristics are typical of Lactobacillus species (Kandler & Weiss, 1986; Rogosa & Sharpe, 1960). Several characteristics eliminated the other 'regular, nonsporing, Gram-positive rods' as possible placements for the isolates. Carnobacterium species do not grow on acetate agar (Collins et al., 1987). Erysipelothrix Rosenbach 1909 (Jones, 1986), Brochothrix Sneath & Jones 1976 (Sneath & Jones, 1986) and Listeria Pirie 1940 (Seeliger & Jones, 1986) often form filaments and have a G + C range of 36–40 mol %; the latter two genera are also catalase-positive. Kurthia Trevisan 1885 (Keddie & Shaw, 1986), Caryophanon Peshkoff 1939 (Trentini, 1986) and Renibacterium Sanders & Fryer 1980 (Sanders & Fryer, 1986) are strictly aerobic organisms. The granules revealed by Gram-staining are common in homofermentative Lactobacillus spp. (Kandler & Weiss, 1986). The new isolates distinctly differ from the facultative anaerobic, lactic-acid-producing genera Staphyloccoccus Rosenbach 1884 (Kloos & Schleifer, 1986), Streptococcus Rosenbach 1884 (Hardie, 1986), Leuconostoc van Tieghem 1878 (Garvie, 1986a) and Pediococcus Claussen 1903 (Garvie, 1986b), which exhibit definite coccal morphology. Also, classification of the new isolates as Bifidobacter was ruled out because this genus is strictly anaerobic, produces acetic acid as well as lactic acid.
and has a G+C range of 59–70 mol% (Scardovi, 1986).

Phylogenetic analysis in the present study established that the isolates are members of the genus *Lactobacillus*. It is generally agreed that organisms exhibiting differences in G+C contents no greater than ±2% might be members of the same species (Johnson, 1973). According to Kandler & Weiss (1986) *L. plantarum, L. paracasei, L. casei, L. coryniformis, L. delbrueckii, L. pentosus* and *L. rhamnosus* are homofermentative *Lactobacillus* species with G+C contents within 2% of the 48 mol% values of the new isolates. *L. amylophilus* is another species that meets this criterion (Nakamura & Crowell, 1979). The DNA relatedness data in Table 2 indicate that the simmondsin-degrading isolates were unrelated to the reference strains of these established species. The new isolates are homofermenters and differ from the other homofermenters in a number of ways (Table 1). Whilst both simmondsin-degraders and *L. rhamnosus* grow at 15 and 45 °C, the latter species produces only L-(-)-lactic acid and does not ferment melibiose or raffinose. Additionally, in contrast to the new isolates, *L. amylophilus, L. casei* subsp. *casei, L. delbrueckii* and *L. coryniformis* do not produce both D-(-)- and L-(+)-lactic acid and, except for *L. coryniformis*, do not ferment melibiose or raffinose. Furthermore, *L. amylophilus* hydrolyses starch, a trait not shown by the simmondsin-degraders. Unlike the new isolates, *L. plantarum, L. pentosus, L. coryniformis, L. amylophilus, L. casei* and *L. paracasei* do not grow at 45 °C. The inability to ferment D-xylulose further distinguishes the simmondsin-degraders from *L. pentosus*. In contrast to the new isolates, *L. paracasei* does not ferment melibiose or raffinose. Furthermore, *L. plantarum* does not ferment L-rhamnose, an activity exhibited by some of the new isolates.

The evidence presented indicates that the simmondsin-degrading *Lactobacillus* strains are members of a new species, for which the name *Lactobacillus arizonensis* is proposed. In spite of some minor differences in sugar fermentation patterns among the isolates, their consistently high DNA relatedness suggest that all isolates are members of single species.

**Description of Lactobacillus arizonensis** sp. nov.

*Lactobacillus arizonensis* (ari.zon.en.sis. L. gen. n. arizonensis named after the state in the United States where it was isolated).

Cells are rods, 1 x 4.0–5.0 µm in size, which occur singly and in short chains. Gram-positive and non-motile. Endospores are not produced. Colonies on agar are white, convex, smooth, circular and opaque. In broth, growth causes turbidity which clears after a few days due to settling of cells. Acid is produced from cellobiose, D-fructose, D-galactose, D-glucose, lactose, maltose, D-mannitol, D-mannose, melibiose, raffinose, D-ribose, salicin, D-sorbitol, sucrose and trehalose. Some strains may ferment L-(-)-arabinose and rhamnose, but D-xylulose is not fermented. No gas is produced from D-glucose. L-(+)- and D-(−)-lactic acids are the only organic acids produced. Catalase is not produced. Facultatively anaerobic. Temperature relations are as follows: optimum, 35–40 °C; minimum, 10–15 °C; maximum, 45–50 °C. G+C content is 48 mol%. Isolated from jojoba meal fermentations. The type strain is NRRL B-14768 (= DSM 13273).

**ACKNOWLEDGEMENTS**

The authors are grateful to Michael Cotta for the lactic acid analyses and to Jill Pearsall for general technical help.
