Many investigations have demonstrated that alcohol administration induces generation of reactive oxygen species in the liver leading to oxidative injury.1,2 After the pioneering report of Di Luzio3 showing that supplementation of antioxidant inhibited acute alcohol-induced fatty liver and lipid peroxidation, antioxidant supplementation has been widely applied to prevent alcoholic liver injury in both animal models and human clinical trials. Most studies suggest that alcohol-induced liver injury could be reduced by supplementation with antioxidants, including glutathione (GSH) precursor, vitamins E and C, and some trace elements.4,5

Metallothionein (MT) is a highly conserved, low molecular weight, cysteine-rich protein. MT shares important features with GSH. The sulfhydryl groups of GSH and MT are the major thiolate pool in the cell. However, the thiolate groups in MT are preferential targets for H2O2 compared to GSH.6 Kinetic studies demonstrated that MT was 38.5-fold more potent than GSH on a molar basis in preventing HO•-induced DNA degradation.7 Recent studies in this laboratory have demonstrated that MT provides effective protection from ethanol-induced oxidative hepatotoxicity in vivo.8

The mechanisms by which MT functions as a potent antioxidant are poorly understood. MT is the only known protein that is implicated in zinc distribution.9 Many studies have demonstrated that zinc-induced MT expression provides effective protection against hepatotoxicity induced by acetaminophen,10 carbon tetrachloride,11,12 doxorubicin,13 and GSH depletors.14 However, zinc-induced protection is not always correlated with MT elevation.15 On the other hand, increasing evidence indicates that zinc has antioxidant properties by inhibition of HO• formation through antagonism of redox-transition metals.16 Most importantly, zinc is released from MT under oxidative stress.17,18 Therefore, it is of great interest to determine whether zinc mediates the antioxidant action of MT. This has to be determined unequivocally by using unique experimental approaches such as MT-transgenic and MT-null mouse models. MT-null mice (MT-KO) lacking MT-I and MT-II, the only mouse hepatic MT isoforms,
have been produced by a gene-targeting technique. This model thus serves as a valuable tool to reveal the link between zinc and MT in cytoprotection from oxidative injury.

This study was undertaken to determine the role of zinc in MT protection against ethanol-induced hepatotoxicity and the possible mechanisms. MT-KO mice and wild-type controls were treated with three doses of alcohol with or without zinc pretreatment. Hepatic MT, zinc concentrations, lipid peroxidation, and reduced glutathione concentrations were determined by biochemical methods. Hepatic histopathological and ultrastructural changes were observed by light and electron microscopy.

Materials and Methods

Animals

Homozygous MT-KO mice were obtained from Jackson Laboratories (Bar Harbor, ME) and were produced on the 129/Sv genetic background. Both MT-KO and 129/Sv wild-type (WT) controls were housed in the animal quarters at the University of Louisville Research Resources Center. They were maintained at 22°C with a 12-hour light/dark cycle and had free access to rodent chow and tap water. The experimental procedures were approved by the Institutional Animal Care and Use Committee, which is certified by the American Association of Accreditation of Laboratory Animal Care.

Ethanol Administration

A binge drinking mouse model developed by Carson and Pruett was followed for ethanol challenge. This model was designed to achieve blood alcohol levels, behavioral effects, and physiological changes comparable to human binge drinking. MT-KO as well as WT mice at the age of 9 weeks were divided into four groups in a 2 x 2 factorial design (+/− zinc, +/− ethanol): control, ethanol treatment, zinc treatment and zinc/ethanol treatment. Zinc chloride (ZnCl₂) was administrated by intraperitoneal injection at a dosage of 5 mg Zn/kg once a day for 3 days before ethanol administration. Three doses of ethanol (25%, w/v) (Aldrich, Milwaukee, WI) at 5 g/kg were administrated by gavage at 12-hour intervals. Control mice received isocaloric maltose solution. At 4 hours after the last ethanol dosing, the mice were anesthetized with sodium pentobarbital (0.05 mg/g body weight) (Abbott Laboratories, North Chicago, IL). Blood was drawn from the dorsal vena cava and sera were obtained by centrifugation with saline and fixative (see below).

MT Assay

Tissue MT concentrations were determined by a cadmium-hemoglobin affinity assay. Briefly, liver tissues were homogenized in 4 volumes of 10 mmol/L Tris-HCl buffer, pH 7.4 at 4°C. After centrifugation of the homogenate at 10,000 × g for 15 minutes, 200 μl of supernatant was transferred to microtubes for MT analysis as described previously.

Determination of Zinc

Hepatic zinc concentrations were determined by induc-tively coupled argon plasma emission spectroscopy (Jarrel-Ash, Model 1140, Waltham, MA) after lyophilization and digestion of the tissues with nitric acid and hydrogen peroxide. Zinc concentrations in the liver were expressed as μg/g dry tissue.

Light Microscopic Examination

Liver tissues were cut into ~3-mm-thick slices and fixed with 10% neutral formalin. The tissue slices were embed-ded in paraplast. Tissue sections of 5 μm were stained by hematoxylin and eosin (H&E) and observed with a Nikon Eclipse E400 light microscope.

Electron Microscopic Examination

To observe ethanol-induced ultrastructural changes by conventional electron microscopy, livers were fixed in situ by vascular perfusion with Karnovsky’s fixative (2% para-formaldehyde and 2.5% glutaraldehyde in 0.1 mol/L sodium cacodylate buffer, pH 7.4) and post-fixed in 1% osmium tetroxide. Ultra-thin sections were stained by uranyl acetate and lead citrate and observed with a Philips transmission electron microscope.

Determination of GSH Concentrations

Liver GSH concentrations were assayed by the glutathi-one-disulfide reductase and 5′-dithiobis (2-nitrobenzoic acid) recycling assay. Briefly, liver tissue was homogenized with 5% sulfosalicylic acid and centrifuged at 10,000 × g for 5 minutes. The supernatant was divided into two aliquots. One aliquot was directly used to measure total glutathione and the other aliquot was first treated with 2-mercaptoethanol. The reaction mixture was placed in a water bath at 95°C for 1 hour.
After cooling on ice, 1.0 ml of distilled water and 5.0 ml of butanol/pyridine mixture (15:1, v/v) were added and vortexed. After centrifugation at 10,000 × g for 10 minutes, absorbance of the resulting lower phase was determined at 532 nm. The TBARS concentration was calculated using 1,1,5,5-tetraethoxypropane as standard.

**Statistics**

All measurements are expressed as mean ± SD (n = 5–8). The data were analyzed by analysis of variance and Tukey’s Honestly Significant Difference (HSD). Differences between groups were considered significant at P < 0.05.

**Results**

**Hepatic MT Concentrations**

As shown in Figure 1, MT concentrations in the liver of WT mice were elevated about 7-fold by zinc treatment or zinc plus ethanol treatment. However, ethanol per se did not induce a significant increase in hepatic MT concentrations. In the MT-KO mice, hepatic MT concentrations were very low and were not affected by ethanol, zinc, or zinc plus ethanol treatments. The MT level in the MT-KO mice has been reported to represent the assay background but not MT protein content in the liver.25

**Hepatic Zinc Concentrations**

Zinc concentrations in the liver of MT-KO mice were lower than in WT mice before and after ethanol treatment, although the differences were not significant (Figure 2). Zinc treatment led to increases in hepatic zinc concentrations in both WT and MT-KO mice, but this elevation was significantly higher in the WT mice. In mice treated with zinc plus ethanol, hepatic zinc concentrations were lower in both WT and MT-KO mice compared to their zinc-treated counterparts.

**Prevention of Ethanol-Induced Histopathological Changes by Zinc Pretreatment**

The prominent histopathological change induced by ethanol in the WT mouse liver was microvesicular steatosis (Figure 3). However in MT-KO mice, ethanol caused apparent necrosis as suggested by cell enlargement, vacuolization, and nuclear dissolution. Pretreatment with zinc apparently inhibited ethanol-induced hepatic damage in both WT and MT-KO mice to the same extent; only minor steatosis was observed in livers pretreated with zinc.

**Prevention of Ethanol-Induced Ultrastructural Changes in Hepatocytes by Zinc Pretreatment**

In comparison to the hepatocytes of normal controls (Figure 4, A and B), ethanol administration caused lipid droplet accumulation and mild disorganization of rough endoplasmic reticulum and condensation of chromatin condensation in the WT mice (Figure 4C). However, the same ethanol treatment caused much more severe ultrastructural changes in MT-KO mice (Figure 4D). The prominent abnormalities of ethanol-treated MT-KO mouse hepatocyte include condensation and degeneration of mitochondria and rough endoplasmic reticulum, focal degeneration of cytoplasm, and condensation of chromatin. The ultrastructure of zinc-treated livers was similar to the normal controls (Figure 4, E and F). Pretreatment with zinc dramatically inhibited ethanol-induced abnormalities in both WT and MT-KO mice (Figure 4, G and H). The
organelles and nuclei of hepatocytes were basically normal and the size and number of lipid droplets were decreased, although rough endoplasmic reticulum was scanty in the MT-KO mice.

Inhibition of Ethanol-Induced Hepatic GSH Depletion by Zinc Pretreatment

There was no significant difference in hepatic GSH concentrations between MT-KO and WT mice, though MT-KO mice had relatively lower GSH concentrations (Figure 5). In response to ethanol exposure, hepatic GSH concentrations significantly decreased in both WT and MT-KO mice. Zinc treatment significantly inhibited ethanol-induced decreases in hepatic GSH concentrations in both WT and MT-KO mice, but the inhibition was more profound in the WT mouse liver.

Inhibition of Ethanol-Induced Hepatic Lipid Peroxidation by Zinc Pretreatment

Ethanol-induced hepatic lipid peroxidation was assessed by measuring TBARS concentrations. As shown in Figure 6, ethanol administration caused a significant increase in lipid peroxidation in the livers of both WT and MT-KO mice. The extent of ethanol-induced lipid peroxidation was significantly greater in the MT-KO mice. Pretreatment with zinc significantly suppressed ethanol-induced lipid peroxidation in both WT and MT-KO mice, although the hepatic TBARS content in the MT-KO mice was higher than in the WT mice.

Discussion

The data obtained from this study demonstrate that MT-KO mice are more sensitive than WT mice to ethanol-induced hepatotoxicity. Ethanol administration induced fat droplet accumulation in both MT-KO and WT mice. However, necrotic degeneration and organelle abnormalities were observed only in MT-KO mice. In association with hepatic pathological changes, ethanol administration induced marked decreases in hepatic GSH concentrations and increased hepatic lipid peroxidation. The ethanol-induced hepatotoxic responses were significantly suppressed in both MT-KO and WT mice by zinc pretreatment. These findings indicate that zinc functions in protection from alcoholic liver injury. The protective action of zinc is independent of MT, but slightly decreased in the WT mouse livers. This change indicates that MT plays a critical role in maintaining high levels of zinc in the liver.

MT has been repeatedly shown to provide protection from oxidative injury in multiple organ systems. In investigations using MT-overexpressing transgenic mice, zinc has been often ascribed to MT induction, there are also evidence showing that zinc-induced tolerance to carbon tetrachloride hepatotoxicity is not due to the chloromethyl radical-scavenging action of MT. It thus remains to be determined whether zinc functions as a protective agent independent of MT or through the production of MT.

The use of MT-KO mice in the present study provided an unequivocal approach to address the question above. In the MT-KO mice, MT concentrations in the liver were very low and were not elevated by zinc treatment. Zinc concentrations in the liver of MT-KO mice were lower than in the WT mice, indicating a lack of MT-bound zinc in the MT-KO mouse liver. In response to zinc supplementation, zinc concentrations in the liver of both WT and MT-KO mice were elevated, however more profound elevation was observed in the WT mouse liver, correlating with MT elevation. Ethanol treatment decreased zinc concentrations in the liver of MT-KO mice, but much less in the WT mice. These changes likely reflect a decrease in the non-MT-bound zinc pool in the MT-KO mice and the buffering role of MT in preventing total loss of zinc in the livers of WT mice. Interestingly, the elevated zinc concentration in the zinc supplemented MT-KO mouse livers was significantly decreased in response to ethanol treatment, but slightly decreased in the WT mouse livers. This change indicates that MT plays a critical role in maintaining high levels of zinc in the liver especially under stress conditions.

The changes in zinc concentrations in the liver apparently affected pathological changes induced by ethanol treatment. However, it appeared that there might be a cytoprotective threshold level, above which varying concentrations of zinc would produce the same protection. As demonstrated by the results, in comparison with WT mice, MT-KO mice were more sensitive to alcoholic hepatotoxicity, which correlated with lower concentrations of zinc in the MT-KO mouse liver. Zinc supplementation significantly suppressed the cellular and subcellular damages induced by ethanol in both WT and MT-KO mice. It is specifically noteworthy that the MT concentrations were not increased, but zinc concentrations were elevated in the MT-KO mouse livers. Therefore, the protection was related to zinc per se, but not dependent on MT.
MT in the liver? MT is the only known protein responsible for cellular zinc distribution, and each MT molecule can bind seven zinc atoms by its thiolate ligands. The MT-bound zinc can be released as a consequence of stress-induced changes in cellular redox state.\(^{17,18}\) Zinc released from MT may function as a mediator of MT cytoprotection because zinc itself has antioxidant properties. Therefore, high levels of MT in the liver at least maintain high levels of liver zinc.

Oxidative stress has been shown to mediate the pathogenesis of alcoholic liver disease.\(^{1,2}\) We have observed that MT provides cytoprotection through inhibition of ethanol-induced oxidative stress.\(^{8}\) If zinc mediates MT antioxidant action, hepatic protection by zinc from ethanol-induced oxidative stress should be observed. Therefore, the effect of zinc on ethanol-induced lipid peroxidation and GSH depletion were measured. The results demonstrate that zinc significantly suppressed ethanol-induced lipid peroxidation and GSH depletion in both WT and MT-KO mice. These observations agree with many previous studies. For example, zinc supplementation significantly suppressed hepatic lipid peroxidation induced by a variety of chemicals, including ethanol,\(^{41}\) carbon tetrachloride,\(^{11,12}\) and dimethylnitrosamine.\(^{42}\) Hepatic GSH depletion by carbon tetrachloride and dimethylnitrosamine was also attenuated by zinc administration.\(^{12,42}\) In these studies, however, zinc was used as an inducer for MT production and hepatic protection was ascribed to MT induction. The present study aimed to separate the role of zinc and MT by using the MT-KO mouse model. It clearly showed that zinc itself inhibited lipid peroxidation and GSH depletion induced by ethanol in the liver.

Although the mechanisms are largely unclear, the antioxidant actions of zinc are thought to involve the antagonism of redox-active transition metals such as iron and copper. Many studies have demonstrated that trace amounts of redox-active metals are required to catalyze the formation of HO\(^{•}\) and other radicals. Metal-catalyzed formation of HO\(^{•}\) can result in the abstraction of hydrogen from unsaturated fatty acid or protein leading to lipid peroxidation or protein oxidation.\(^{16}\) Zinc has been shown to antagonize the catalytic properties of the redox-active metals and inhibit HO\(^{•}\) and O\(^{2–}\) formation in different systems. In a chemical system, zinc was found to reduce the HO\(^{•}\) formation from iron and cysteine.\(^{43}\) A study using a biochemical system has demonstrated that zinc suppresses iron mediated, xanthine/xanthine oxidase-induced membrane peroxidation of erythrocytes.\(^{44}\) In a cardiac perfusion system, zinc was shown to reduce post-ischemic formation of HO\(^{•}\) in association with decreased copper content in the heart.\(^{45}\) In the pathogenesis of alcoholic liver injury, iron has been a major determinant. Many investigations have demonstrated ethanol administration increases the redox-active iron concentration in the liver, leading to lipid peroxidation.\(^{46}\) The present study demonstrated that zinc itself indeed has antioxidant action. However, further investigations are required to determine whether the antioxidant action of zinc is related to antagonism of redox-active iron overloaded by ethanol administration.

**Figure 4.** Ethanol-induced ultrastructural changes in the hepatocytes of WT and MT-KO mice. WT mice: control (A), ethanol (C), zinc (E), and zinc/ethanol (G). MT-KO mice: control (B), ethanol (D), zinc (F), and zinc/ethanol (H). In comparison with WT mice, ethanol-induced ultrastructural damages were more severe in the liver of MT-KO mice. In particular, focal cytoplasmic degeneration and organelle condensation were observed in the MT-KO mice. These ultrastructural changes were improved by zinc pretreatment, although rough endoplasmic reticulum was scanty in the MT-KO mice. N, nucleus; M, mitochondria; RER, rough endoplasmic reticulum; L, lipid droplets; FCD, focal cytoplasmic degeneration. Magnification, \(\times7500\).

**Figure 5.** Hepatic GSH concentrations in the WT and MT-KO mice and the effect of ethanol treatment. Cont, control; EtOH, ethanol. Results are means ± SD (n = 5–8). The data were analyzed by analysis of variance and Tukey’s HSD. Significant difference (P < 0.05) is identified by letter superscripts.

**Figure 6.** Hepatic lipid peroxidation in the WT and MT-KO mice. Lipid peroxidation was quantified by measuring thiobarbituric acid-reactive substance (TBARS). Cont, control; EtOH, ethanol. Results are means ± SD (n = 5–8). The data were analyzed by analysis of variance and Tukey’s HSD. Significant difference (P < 0.05) is identified by different letter superscripts.
In conclusion, this study demonstrates that zinc is directly involved in the protection of liver from alcoholic injury. However, MT is critical to maintain high levels of zinc in the liver. The coordination between zinc and MT is thus that MT retains high levels of zinc in the liver under physiological conditions and releases zinc under oxidative stress conditions, leading to potent antioxidant action.
