### Abstract
Swine (Sus scrofa) manure can serve as a fertilizer source for crop production, but it typically contains more P relative to N than the crop requires, creating the potential for P losses in runoff. A 3-year study was conducted to compare runoff losses of NO$_3$-N, NH$_4$-N, total N, dissolved P, and total P under natural rainfall conditions from no-tillage sorghum plots [Sorghum bicolor (L.) Moench] receiving inorganic fertilizer, manure from swine fed low-phytate corn (Zea mays L.) diet, or manure from swine fed a traditional corn diet. Runoff (26.5 mm in 1999, 14.2 mm in 2000, and 1.6 mm in 2001), sediment loss (2.9 kg ha$^{-1}$ in 1999, 0.9 kg ha$^{-1}$ in 2000, and 0.4 kg ha$^{-1}$ in 2001), and runoff nutrient losses differed among years but were similar among treatments within a year. Runoff losses of NO$_3$-N (5.3 g ha$^{-1}$ in 1999, 1.0 g ha$^{-1}$ in 2000, and 2.6 g ha$^{-1}$ in 2001), NH$_4$-N (2.9 g ha$^{-1}$ in 1999, 0.6 g ha$^{-1}$ in 2000, and 5.6 g ha$^{-1}$ in 2001), total N (89.7 g ha$^{-1}$ in 1999, 8.4 g ha$^{-1}$ in 2000, and 100.2 g ha$^{-1}$ in 2001), dissolved P (1.5 g ha$^{-1}$ in 1999, 0.5 g ha$^{-1}$ in 2000, and 3.1 g ha$^{-1}$ in 2001), and total P (3.8 g ha$^{-1}$ in 1999, 0.9 g ha$^{-1}$ in 2000, and 3.5 g ha$^{-1}$ in 2001) from these plots represented less than 1% of that applied each year. Although use of low-phytate corn reduces manure P content, it did not decrease runoff P under these no-tillage conditions.

Nutrient management, manure management, water quality, conservation tillage.

### Materials and Methods

#### Swine Feed Preparation

Corn exhibiting the low-phytate trait (Pioneer variety X1127PP) and the same variety without the low-phytate trait (Pioneer variety Alicia) were grown under irrigation near Shelton, NE, in 1998. Recommended practices for irrigation, fertilizer application, and pest control were used to optimize yield. The stands were harvested and stored separately until used as feed. The two corn sources were used to prepare feed appropriate for a starter-phase swine diet in the spring of 1999, 2000, and 2001. Each year, the two diets were fed to swine in elevated pens with 10 pigs per pen. Each diet was fed to all pigs in six randomly assigned pens. Trays were placed under each pen, and slurry (manure and urine) was collected. Slurry from swine fed each of the two diets was stored separately until needed for field application. A representative TC slurry sample contained 3.6% ± 0.9% dry matter and on a dry-weight basis.
had an N concentration of 108.8 ± 13.0 g kg⁻¹ and a P concentration of 33.6 ± 11.1 g kg⁻¹. A representative LPC slurry sample contained 7.2% ± 0.6% dry matter and on a dry-weight basis had an N concentration of 90.1 ± 11.6 g kg⁻¹ and a P concentration of 19.8 ± 1.2 g kg⁻¹. Approximately 60% of manure P is water extractable in both manure types (Wienhold and Miller, 2004).

**Site Description and Experimental Design**

The field site was located at the Rogers Memorial Research Farm 18 km east of Lincoln, NE. Soil at the Rogers Farm was an Aksarben (formerly Sharpsburg) silty clay loam (fine smectitic, mesic, Typic Argiudoll) on a 3% to 5% slope. When this study was initiated, the soil had a total N concentration of 1.6 g kg⁻¹, an organic C concentration of 10.2 g kg⁻¹, Bray P concentration of 7.8 mg kg⁻¹, a bulk density of 1.16 g cm⁻³, and a pH of 5.7 in the 0- to 15-cm depth (Wienhold, 2005).

The site has been in a no-tillage winter wheat (Triticum aestivum L.), soybean [Glycine max (L.) Merr], sorghum (Sorghum bicolor (L.) Moench) rotation for more than 10 years and was in the sorghum phase of the rotation in the year before the initiation of this study. The site had no known history of manure application. Nine runoff plots (3.6 × 9.7 m) were established by installing metal borders on the upslope end and sides and a collection trough on the downslope end. The long side of the plot was parallel to the slope. Runoff and sediment generated from a plot during a precipitation event flowed into the collection trough, through a pipe, and into a container. Three nutrient treatments (inorganic fertilizer, LPC manure, and TC manure) were assigned to the plots in a completely randomized design with three replications. The inorganic fertilizer treatment received 120 kg N ha⁻¹ as NH₄NO₃ and 30 kg P ha⁻¹ as superphosphate. This treatment served as the control because sorghum biomass production is reduced with no fertilization (Paschold et al., 2008b) and reduced surface crop residue could potentially result in increased runoff. In addition, previous research has documented that P contained in fertilizer and manure contribute more to runoff loss of P than antecedent soil P (Smith et al., 2004b). Both manures were added at rates required to meet the N needs of sorghum, assuming 70% of the N in the manure was available to the crop during the growing season (Koelsch and Shapiro, 1997). The two manures differed in nutrient concentration (Wienhold and Miller, 2004). This difference resulted in different P application rates (Table 1). Manure nutrient concentration was determined before application for estimating application rates and also at the time of application for calculation of actual application rates (Table 1). Differences in nutrient content between these two sampling times caused by changes during storage and variation in mixing of the slurry before sample collection affected the actual amount applied. Sorghum was direct-seeded into the previous year residue, and was in the sorghum phase of the rotation in the year before sample collection affected the actual amount applied.

**Runoff, Sediment, and Chemical Analysis**

Precipitation was recorded by an automated rain gauge (Onset Corp, Bourne, MA) at the site. For precipitation events that generated runoff, the volume of runoff was recorded, sediment was resuspended, and duplicate samples were collected for determination of sediment content and chemical analysis. Samples were collected for all runoff events from the time nutrient treatments were applied in the spring until crop harvest in the fall of each year. For each runoff event, a subsample of runoff was placed in a drying bottle, weighed, dried, and reweighed to determine sediment mass. Runoff and erosion amounts were calculated based on the volume of water, mass of sediment, and plot area. Chemical analysis included colorimetric determination of total P in nitric acid-perchloric acid digests (Johnson and Ulrick, 1959), total N using the Dumas method (Tate, 1994), electrical conductivity using a conductivity meter, pH using a glass electrode (Smith and Doran, 1996) in unfiltered subsamples, dissolved P using the phosphomolybdate blue method (Murphy and Riley, 1962), and inorganic N using the Cd reduction method (Mulvaney, 1996) in subsamples that were centrifuged and filtered. Nutrient loss was calculated based on nutrient concentration, runoff volume, and plot area. Because the amount of N and P applied differed among treatments, nutrient loss was also expressed as a percentage of applied N and P.

**Statistical Analysis**

Runoff, sediment, and nutrient loss were compared among treatments by a completely random repeated-measures model in PROC MIXED of SAS (Littell et al., 1996). Differences were considered significant at the 0.05 probability level. Differences among means were determined by pairwise comparisons made with the DIFF option of the LSMEANS statement. The Tukey adjustment option of the LSMEANS statement was used to protect the experiment-wise error rate.

**RESULTS**

Precipitation received during the runoff assessment period of each year was similar (32 cm in 1999, 30 cm in 2000, and 35.5 cm in 2001). However, the intensity and duration of individual precipitation events were highly variable. In 1999, nearly half of the precipitation received during the growing season fell during the first two events (Fig. 1). In 2000 and 2001, numerous small precipitation events occurred at the beginning of the growing season. These precipitation patterns are characteristic of the continental climate present in this region (Hershfield, 1961).

The observed precipitation patterns exerted a strong influence on runoff from the plots (Fig. 2). Runoff differed among years \( P < 0.0001 \) and was greatest in 1999 and lowest in 2001. In 1999, the two initial precipitation events generated most of the observed runoff. In 2000, 80% of the observed runoff resulted...

*TC: manure from swine fed a traditional corn diet; LPC: manure from swine fed a low phytate corn diet; IF: inorganic fertilizer.*
from a single precipitation event on Day 150. In 2001, precipitation was characterized by numerous small events that generated minimal runoff. When expressed as a percentage of precipitation received, runoff amounted to 8% of precipitation in 1999, 4% of precipitation in 2000, and less than 1% of precipitation in 2001. In addition to precipitation intensity and duration, management also affects the incidence and volume of runoff. Crop residue retained on the soil surface with no-tillage has been found to maintain soil structure and infiltration capacity (Rousseva, 1989) and contributed to the low runoff volumes measured in this study. Others have also reported low runoff volumes under natural rainfall from untilled plots (Menjoulet et al., 2009).

There was little variation in pH and electrical conductivity among treatments or years. Mean runoff pH was 6.5 ± 0.3, and EC was 0.09 ± 0.06 dS m⁻¹. Based on measured pH and electrical conductivity, the runoff from plots in this study would not be expected to substantially impact receiving water bodies. The near-neutral pH and low electrical conductivity values reflect the low nutrient loads discussed later for runoff in this study.

Flow-weighted concentrations (FWC) of nutrients in runoff from the plots did not differ among treatments (P > 0.05), and there was no interaction between treatment and years (P > 0.05). The FWC of dissolved P was greater in 1999 and 2001 than in 2000 (Table 2). The dissolved P FWC was great enough to contribute to eutrophication of receiving water bodies in all 3 years (Correll, 1998). The FWC of total P was greater in 1999 than in 2000 or 2001. A maximum contaminant level for NO₃⁻N of 10 mg L⁻¹ has been established for drinking water (USEPA, 2006). Although FWC of NO₃⁻N was greater in 1999 than in 2000 or 2001, the maximum contaminant level was not exceeded during the study. Nitrate-N has also been implicated as contributing to the hypoxic zones in aquatic ecosystems at concentrations as low as 2 mg L⁻¹ (Turner et al., 1997). The FWC of NH₄⁺-N and total N was greater in 1999 and 2001 than in 2000. The FWC of NH₄⁺-N in 2001 exceeded the 2.5 mg L⁻¹ concentration identified as adversely affecting aquatic organisms (USEPA, 1986). Flow-weighted concentrations of nutrients tended to be greater in 1999 and 2001 when a significant amount of runoff was generated shortly after treatment application (90% during the first two precipitation events in 1999 and 30% during the first two precipitation events in 2001) compared with 2000 when several precipitation events occurred before runoff occurred. Smith et al. (2007) reported rapid declines in FWC of dissolved P and NH₄⁺-N as a function of days after swine slurry application. Infiltration of slurry into the soil after application and leaching of nutrients into the soil by non-runoff-producing precipitation events reduces the likelihood of subsequent runoff losses of nutrients.

Sediment loss differed among years (P < 0.0001) and was greatest in 1999 and lowest in 2001 (Fig. 3A). Runoff and sediment loss were strongly correlated (Table 3). The mass of sediment lost from these no-tillage plots was small and less than what is considered acceptable for soil conservation. Reduced sediment loss under no-tillage has been well documented (Römkkens et al., 1973). In no-tillage fields, surface soil has greater organic matter content and has an increase in water-stable aggregates that results in increased porosity, higher infiltration, and reduced susceptibility to erosion (Rhother et al., 2002; Pikul et al., 2007).

Dissolved P loss differed among years (P < 0.0001) and was greater in 1999 and 2001 than in 2000 (Fig. 3B). Dissolved P was negatively correlated with runoff (Table 3) and was numerically greater in 2001 when runoff was lowest than in 1999 when runoff was greatest. Total P loss differed among years (P < 0.0001) and was greater in 1999 and 2001 than in 2000 (Fig. 3C). Total P loss was correlated with dissolved P loss (Table 3). Dissolved P was 41% of total P in 1999, 54% of total P in 2000, and 88% of total P in 2001. These percentages are

*Values within a row followed by different letters differ at P < 0.05.*
FIG. 3. Mass of sediment (A), dissolved P (B), total P (C), NO$_3$-N (D), NH$_4$-N (E), and total N (F) lost in runoff as a function of year at the Rogers Memorial Research Farm located near Lincoln, NE. Error bars represent 1 SE. Within a panel, bars with different letters above them are significantly different at $P < 0.05$.

The mass of NO$_3$-N lost in runoff differed among years ($P = 0.003$) and declined in the order 1999 $>$ 2001 $>$ 2000 (Fig. 3D). Mass of NO$_3$-N lost was correlated with runoff, sediment loss, and total P loss (Table 3). Loss of NH$_4$-N and total N in runoff differed among years ($P < 0.0001$) and was greater in 1999 and 2001 than in 2000 (Figs. 3E, F). Mass of NH$_4$-N lost was correlated with loss of dissolved P and total P (Table 3). Total N loss was correlated with loss of dissolved P, total P, NO$_3$-N, and NH$_4$-N (Table 3). When expressed as a percentage of N applied, loss of NO$_3$-N, NH$_4$-N, and total N did not differ among treatments ($P > 0.05$) nor was there a treatment $\times$ year interaction ($P > 0.05$). There were statistical differences among years ($P < 0.001$) in the percentage of NO$_3$-N, NH$_4$-N, and total N applied that was lost; however, the mass of NO$_3$-N, NH$_4$-N, and represented much less than 1% of the P applied on any of the treatments during this study. In contrast, P contained in the grain at harvest represented 25% to 57% of that applied (Paschold et al., 2008b).

The mass of NO$_3$-N lost in runoff differed among years ($P = 0.003$) and declined in the order 1999 $>$ 2001 $>$ 2000 (Fig. 3D). Mass of NO$_3$-N lost was correlated with runoff, sediment loss, and total P loss (Table 3). Loss of NH$_4$-N and total N in runoff differed among years ($P < 0.0001$) and was greater in 1999 and 2001 than in 2000 (Figs. 3E, F). Mass of NH$_4$-N lost was correlated with loss of dissolved P and total P (Table 3). Total N loss was correlated with loss of dissolved P, total P, NO$_3$-N, and NH$_4$-N (Table 3). When expressed as a percentage of N applied, loss of NO$_3$-N, NH$_4$-N, and total N did not differ among treatments ($P > 0.05$) nor was there a treatment $\times$ year interaction ($P > 0.05$). There were statistical differences among years ($P < 0.001$) in the percentage of NO$_3$-N, NH$_4$-N, and total N applied that was lost; however, the mass of NO$_3$-N, NH$_4$-N,
needed to meet P crop requirements, less supplemental N would be necessary than for TC manure. Use of LPC results in more efficient use of P in animal-crop production systems.
