# An Illustrated Guide to Plant Abnormalities Caused by Eriophyid Mites in North America

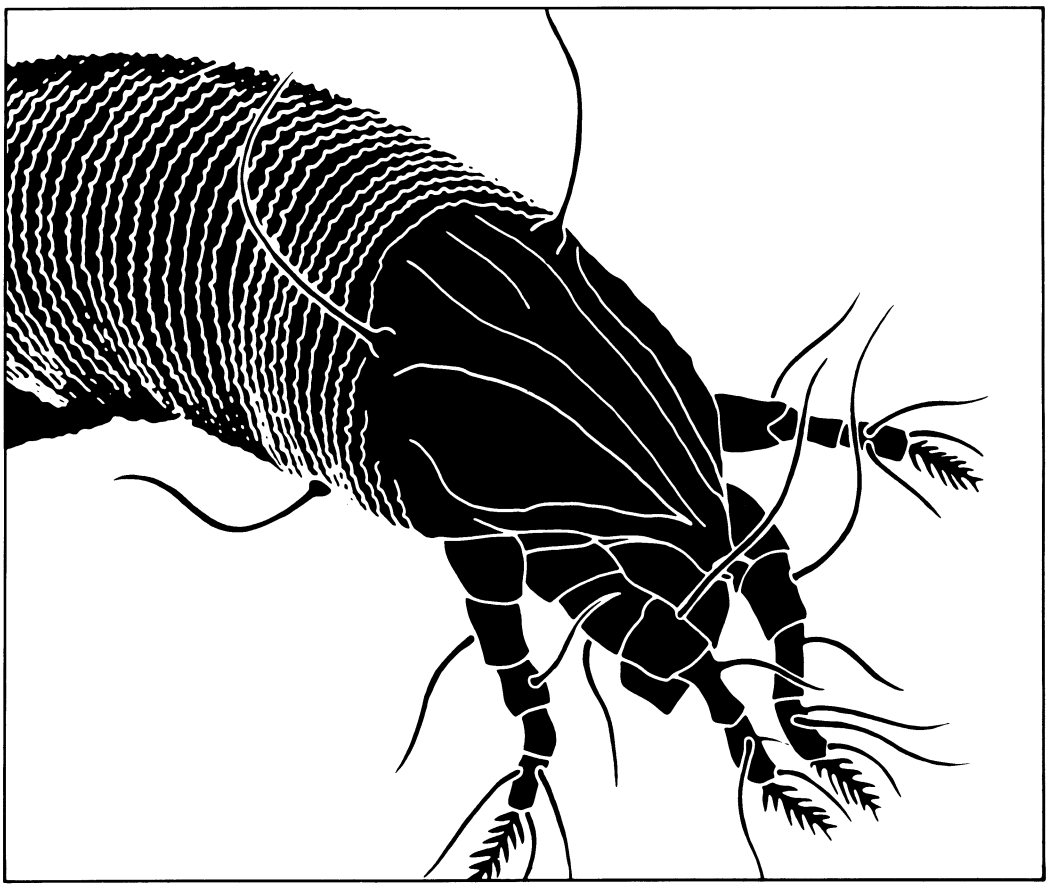
By Hartford H. Keifer, Edward W. Baker, Tokuwo Kono, Mercedes Delfinado, and William E. Styer



## Abstract

Keifer, Hartford H., Baker, Edward W., Kono, Tokuwo, Delfinado, Mercedes, and Styer, William E. 1982. An illustrated guide to plant abnormalities caused by eriophyid mites in North America. U.S. Department of Agriculture, Agriculture Handbook No. 573, 178 pp.

This guide includes taxonomic descriptions of eriophyid mites (Eriophyoidea: Acari), their life histories, distribution, and host data. Characteristic plant injuries, such as galls, erineum, big bud, and witches'-broom, that are caused by these mites are illustrated with color photographs. Selected references are given. This guide will assist in mite identification and mite-induced injury. It is intended for acarologists, entomologists, horticulturists, and those who need to identify mites and to distinguish eriophyid injury from similar symptoms caused by other organisms.

KEYWORDS: Acari, Acarina, erineum, eriophyid mite biology, eriophyid mite description and taxonomy, eriophyid mite-host plant distribution, eriophyid mite-induced injuries, eriophyid mite-plant abnormalities handbook, eriophyid mite-plant galls, eriophyid mite-transmitted mosaic virus, Eriophyidae, Eriophyoidea, witches'-broom.

## Acknowledgment

Without the cooperation of several individuals, this manual could not have been completed. We thank them all for their advice and assistance. We particularly thank the following persons for providing color slides of certain eriophyid mite-plant injuries: H. A. Denmark, Florida Department of Agriculture, Gainesville; E. Doreste, Facultad de Agronomia, Universidad de Venezuela, Maracay; F. P. Freitez, CIARCO, Estacion Experimental de Araure, Acarigua, Venezuela; P. Genty, Industrial Agraria la Palma, Bucaramanga, Colombia; F. H. Haramoto, Entomology Department, University of Hawaii, Honolulu; F. Osman Hassan, Faculty of Agriculture, University of Kartoum, Sudan; L. C. Knorr, Plant Protection Service, FAO-UN, Thailand; D. C. Manson, Horticultural Research Center, Department of Agriculture, Levin, New Zealand; G. R. Nielsen, University of Vermont, Burlington; and K. Wagnon, State of California Department of Food and Agriculture, Sacramento.

R. E. Whitmoyer and G. Berkey, Ohio Agricultural Research and Development Center, Wooster, assisted W. E. Styer in photographing some mites and plant galls. Gisela Rack, Zoologisches Institut und Zoologisches Museum, Universität Hamburg, West Germany, gave us many suggestions and information on catkin galls. We also thank R. Newkirk, Hyattsville, Md., for checking dates of certain eriophyid references.

The University of California Press has permitted inclusion of some gall illustrations from "Mites Injurious to Economic Plants" by Lee R. Jeppson, Hartford H. Keifer, and Edward W. Baker.

# An Illustrated Guide to Plant Abnormalities Caused by Eriophyid Mites in North America

By Hartford H. Keifer, Edward W. Baker, Tokuwo Kono, Mercedes Delfinado, and William E. Styer[1]

Many plant abnormalities are well known to most people. Few persons, however, can recognize the innumerable injuries caused by eriophyid mites (Eriophyoidea: Acari) because no manual or guide exists for the identification and recognition of plant abnormalities and their mite causal agents. This illustrated guide is intended to fulfill this need by (1) providing essential information on plant abnormalities caused by eriophyid mites, (2) identifying these injuries from related forms caused by other organisms, and (3) presenting necessary information on the morphology, habits, and importance of the various eriophyid species that damage plants.

The text summarizes the distinguishing characteristics of both plant injury and mite species, the basic biology of the mite, and the geographical and seasonal distribution. The illustrations of the mites and color photographs of the injuries to the host plants show the characters used in identification. Each plate consists of drawings of an individual mite and certain body structures, with one or more photographs of the typical injuries to the host plants.

The guide includes the mites of the superfamily Eriophyoidea that affect plants of economic or horticultural importance in North America. Certain species occurring elsewhere are also discussed. Because the abnormalities caused by these mites are extremely diverse, it has not been possible to discuss all kinds of injuries in this manual. We have treated those examples most likely to be found in the field.

Terms referring to body structures of the eriophyid mite and certain terms commonly used in descriptive entomology, acarology, and botany are defined in the glossary. Scientific names are given for all plants and mites, and accepted common names are used wherever possible.

[1]Respectively, retired, formerly of State of California Department of Food and Agriculture, Laboratory Services, Sacramento, Calif. 95814; Systematic Entomology Laboratory, Beltsville Agricultural Research Center, Beltsville, Md. 20705; State of California Department of Food and Agriculture, Laboratory Services, Sacramento, Calif. 95814; resident collaborator, Systematic Entomology Laboratory, Beltsville Agricultural Research Center, Beltsville, Md. 20705; and Ohio Agricultural Research Development Center, Wooster, Ohio 44691.

Over 1,250 species of mites are in the superfamily Eriophyoidea; the majority belong in the family Eriophyidae and are of considerable economic importance. They are commonly known as gall, rust, bud, and blister mites or simply eriophyids. Eriophyids are so small that they are almost invisible to the unaided eye, and they are exclusively plant feeders. Members of the Eriophyoidea are soft bodied, wormlike, or spindle shaped and have two body regions, the gnathosoma (mouthparts) and the idiosoma (remainder of body). They are unique among the mites because they have only two pairs of legs. (No other mite has two pairs at any stage of its development.) Morphological development within the superfamily can be rather bizarre (see pls. 1–3).

The life cycle of most eriophyids is relatively simple, but certain species develop through a complicated cycle that includes alternation of generations. The more complex life history is predominant in species that infest deciduous plants and apparently is adapted to seasonal changes in the condition of the hosts. There are two forms, one consisting only of overwintering females called deutogynes and the other consisting of both sexes. The females of the latter are called protogynes. Deutogynes and protogynes of the same species may be conspicuously different morphologically and cause considerable taxonomic confusion. For example, in the walnut-infesting species *Eriophyes brachytarsus* Keifer, the deutogyne and protogyne have each been given a separate scientific name. This

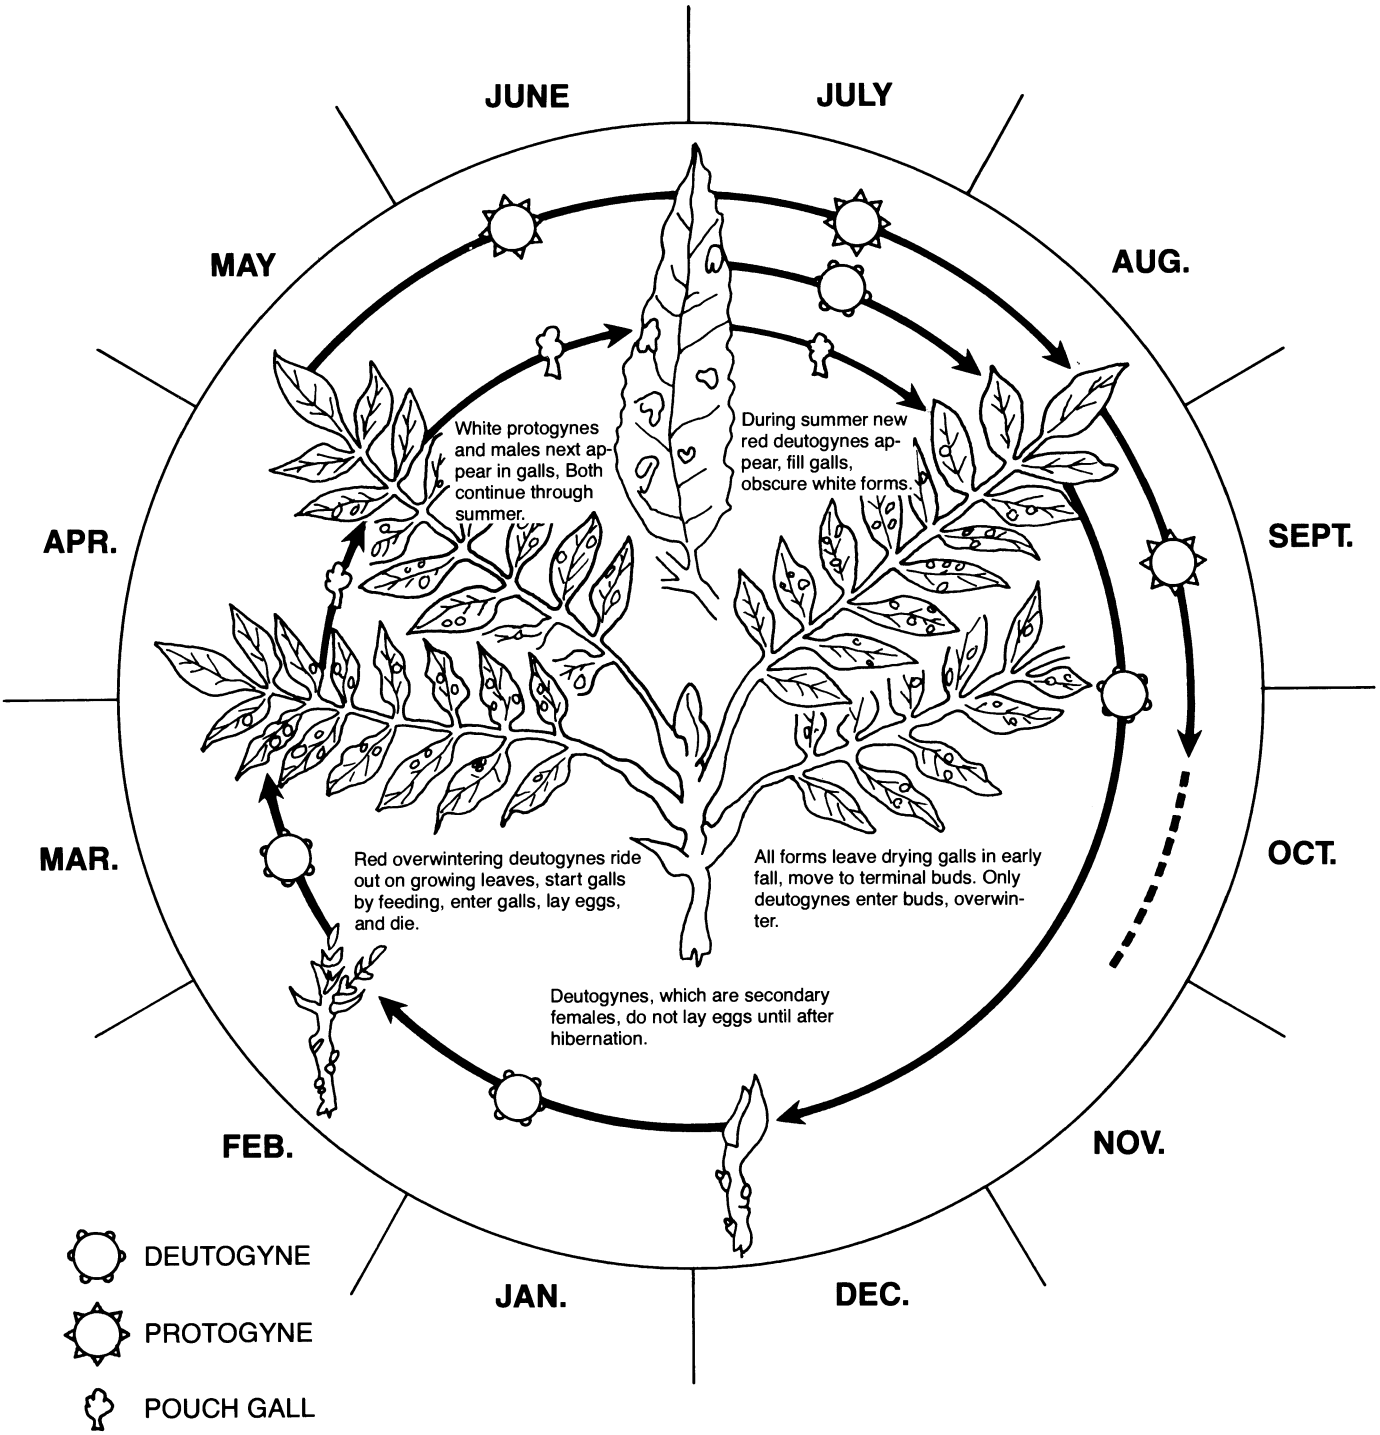

PLATE 4.—Life cycle of *Eriophyes brachytarsus* Keifer, illustrating alternation of generations.

accounts for the confusion and synonyms found for this species, as well as others with a similar life cycle. The typical life cycle of a gall-forming species in which an alternation of generations occurs is illustrated in plate 4.

Eriophyids are one of the most specialized groups of plant feeders. Although symptoms of their feeding run the gamut from simple russeting to complex gall formation, host-mite relationships often appear to be rather specific and probably reflect the high degree of specialization.

Gall formation occurs as a result of mite attack on individual plant cells; it is a localized growth reaction of the host plant to the attack. Common examples are leaf galls, bud galls, and erineum. In some plants, elongation of flower stems and lateral branches is inhibited, causing the development of contorted foliage, flowers, and branches. One of the most conspicuous examples is witches'-broom, which is a cluster of brushlike growth of stunted twigs or branches on trees. Some eriophyid species arrest shoot development, causing leaf sheaths to become enlarged, closely packed, and bunched at stem nodes. Others cause the well-known "big bud," which consists of an aggregation of swollen, thickened scale leaves. Eriophyids also cause an array of nongall abnormalities, such as leaf folding and twisting, blisters, and mosaic virus disease. Russeting and silvering of leaves and redberry disease are also induced by eriophyid feeding.

The various symptoms of injuries caused by eriophyid mites may appear on the following parts of the plant: *Buds, shoots, stems, and twigs*—bud blisters, bud and twig rosette and stunting, discolored buds and bud scales, enlarged buds, premature bud drop, galls, shoot and twig clustering or brooming, shoot, stem, and twig distortion; *flowers*—abnormal shape, blisters, discoloration, failing to open, galls, premature drop; *fruits*—abnormal shape, blisters, damaged seeds, discoloration, galls, hardening, premature drop; and *leaves*—abnormal shape or distortion, blisters, discoloration, erineum, galls, mosaic virus disease, stunting, webbing or coating, and russeting, bronzing, and withering.

The narrow range of acceptable hosts of most eriophyid species also suggests that these mites are highly specialized plant feeders. Although host data for most species are sketchy at best, a surprisingly large number appear to be confined to one species of host plants. Most other eriophyids feed on a few closely related species or genera of plants.

Table 1 includes host plants of economic or horticultural importance, symptoms of injury, and species of mites most likely to cause injury to these plants.

**TABLE 1.—Host plants, symptoms of injuries, and mites**

| Host plant[1] | | Symptom of injury | Mite |

## Host Symptoms of Eriophyid Feeding as Taxonomic Characters

The taxonomic value of host-mite data is considerable. The kind of host plant, the part that is infested, and the characteristics of the resultant injury are useful in making identifications. However, we urge caution when employing eriophyid injury as a diagnostic character because similar plant injury may be induced by other organisms. It is important that all relevant field data be analyzed before attempting to determine the mite taxon in question. Also knowing the correct identity of the host plant is useful since most eriophyid species are relatively host specific. Proper determination of the plant will limit the identity of the mite to a small group of species that occurs on the host.

Symptoms of mite feeding generally are rather specific and have diagnostic merit. For example, general appearance, such as shape, size, color, and position of galls on the host plant, can be very useful. The greatest diversity of galls occurs on leaves. Galls may be elongate, clavate, hemispherical, rounded, or beadlike; they may be scattered haphazardly over the leaf blade, or they may be restricted in the angles between the veins; they may be solitary, coalesced, or in clusters; they may be visible on the upper surface of the leaf, on both surfaces, or on the undersurface only. Galls are also formed on other parts of the plant, including leaf petioles, catkin flowers, flower buds, leaf buds, and leaf axils. Interior gall structures also may provide important characters. Examples of diagnostic differences are illustrated in plates 5–7; others are discussed in Jeppson et al. (*1975*).[2]

Injury symptoms, such as silvering, blistering, leaf coating and webbing, russeting, erineum, and big bud, also are useful taxonomically. Erineum structure has several diagnostic aspects, including position on the leaves, density of hairs, and color; hairs may be elongate, clavate, capitate, unicellular, or multicellular.

[2]The year in italic after authors' names indicates the reference listed on pp. 166–170.

## Economic Importance

Eriophyid mites are important pests of such diverse crops as wheat, citrus, and pomegranates. They have been incriminated as vectors of mosaic viruses on such important crops as wheat, corn, and figs. Injury and disfigurement are commonplace on ornamental trees and shrubs in urban areas.

This manual will aid field workers to recognize eriophyid injury so that control procedures can be undertaken before problems become serious. It should help field personnel make accurate species determinations and thus eliminate misidentifications that often lead to incorrect or ineffective applications of pesticides.

## Eriophyid Research

Eriophyid systematic research is a surprisingly neglected area considering the group's economic importance. The works of H. H. Keifer essentially are the only comprehensive studies of North American eriophyids, but even their emphasis is on California fauna. Because of the enormity of the group, Keifer, of necessity, has had to restrict his efforts almost entirely to descriptions of new species. Very little is known about the biology of eriophyids. Investigations on mite-host interactions are urgently needed. For example, little is known about the mechanisms by which eriophyid feeding provokes proliferation of plant tissues and produces such complex structures as leaf galls, erineum, leaf rolls, and witches'-brooms. Westphal (*1977*) published an excellent paper on the morphogenesis, ultrastructure, and etiology of some eriophyid galls in Europe. This study illustrates the complex organization and wide range of morphogenetic patterns of plant galls caused by eriophyid mites.

Literature on the eriophyids is generally scattered and often fragmented. Information on plant injury is especially difficult to locate. It is often included in general publications on gall morphology and biology (Kendall, *1930;* Felt, *1940;* Shevchenco, *1958;* Buhr, *1964;* Mani, *1964;* Farkas, *1965;* Darlington, *1968*) and may not be seen by most acarologists. Selected eriophyid references are given in Nalepa (*1929*), Jeppson et al. (*1975*), and Westphal (*1977*).

**Aceraceae**

***Acer negundo* L. Box Elder**

**Leaf gall caused by *Eriophyes negundi* Hodgkiss (pl. 8)**

The galls are large, rounded, and peculiarly pouchtype. They develop on the underside of the leaf blade as thickened cavities filled with a dense mass of felty, whitish, unicellular hairs. They protrude on the upper side and have slightly wrinkled domes. Their dimensions are variable. The galls are solitary and widespread on the leaf blade but are not on the veins.

*Eriophyes negundi* is a slender, spindle-shaped, whitish mite; the female measures about 220 microns long and the male 200 microns. The featherclaws are four-rayed; the dorsal shield is marked with longitudinal ridges; the hysterosoma of the male and female (protogyne) is entirely covered with microtubercles, whereas that of the overwintering female (deutogyne) has microtubercles only on the ventral side; and the coverflap of the female genitalia has longitudinal ribs. The life cycle apparently involves alternation of generations. The mites usually are found in the galls until the leaves mature.

Specimens were collected in galls on box elder in New York, Illinois, and Canada and recently in Ohio. Hodgkiss (*1930*) reported two species of *Phyllocoptes* in galls of box elder in New York; they should not be confused with *E. negundi.*

References: Hodgkiss, *1913: 423; 1930: 35–37.*

**Aceraceae**

***Acer rubrum* L. Red Maple**

***Acer saccharinum* L. Silver Maple**

**Leaf gall caused by *Vasates quadripedes* Shimer (pl. 9)**

The mite causes a pouch gall type known as bladder gall, which is periodically common and abundant on the upper leaf surface of red and silver maples. The galls on the latter are variable in shape, rounded or elongate. Each has a slender short stem or neck. The length varies from 1.5 to 5 mm. They are solitary and are usually crowded and numerous at the basal part of the leaf blade in the angles between the larger veins. The exterior of the galls appears wrinkled and glossy. They change from yellowish green or dark green to pink, to brown, to black. The interior is hollow, and the exit hole, which is on the underside of the leaf, is lined with unicellular whitish hairs. In heavy infestations, the leaves become curled, form cylindrical rolls, and drop prematurely. The galls on red maple differ in size and form. They are smaller, 1 to 2 mm, somewhat beadlike, and without a basal constriction or neck.

*Vasates quadripedes* is a spindle-shaped, whitish mite, measuring 170-220 microns long. The dorsal shield is produced anteriorly, and the dorsal setae are directed backward. The overwintering female differs by having a smooth dorsal shield and genital coverflap; it also lacks microtubercles on the dorsum of the hysterosoma; and the featherclaws are palmate and five-rayed. The male and female (protogyne) have a design on the dorsal shield, and microtubercles are over the entire hysterosoma; the featherclaws of the male are four-rayed; those of the protogyne are five-rayed and are not palmate; and the coverflap of the female genitalia is ribbed.

The life history apparently involves alternation of generations. The mites inhabit the galls throughout the summer and begin to migrate to trunk and branches as the galls become discolored. They overwinter under bark scales. An inquiline in the galls, *Eriophyes confusus* Hodgkiss, is probably the protogyne of *V. quadripedes.*

*Vasates quadripedes* is found on red and silver maples in the United States and Canada. In addition to bladder galls, Hodgkiss (*1913*) described four species of eriophyids that are associated with erineum on leaves of red maple in New York. They are *Eriophyes major* Hodgkiss, *E. minutissimus* (Hodgkiss), *E. ornatus* Hodgkiss (now a synonym of *E. major*), and *E. quinquilobus* (Hodgkiss). And in erineum on leaves of silver maple, *E. aceris* Hodgkiss is abundant. The erineum patches, which are on the undersurface of the leaves, are pale greenish or greenish yellow, often with a reddish tint, and later red. In July most of the erineum turns brown and becomes dry.

**Aceraceae**

***Acer saccharum* Marsh. Sugar Maple**

**Leaf gall caused by *Vasates aceriscrumena* (Riley) (= *Phytoptus acericola* Garman) (pl. 10)**

Another common and abundant pouch gall that develops on the upper surface of sugar maple leaves is the spindle or finger gall, which is caused by *Vasates aceriscrumena*. The gall is distinguished from that of *V. quadripedes* Shimer by its form, position, color, and texture. The galls are solitary, elongate, with pointed or truncate apices, or spindle shaped. They are variable in size, up to 5 mm in length, and tend to crowd at the apical half of the leaf blade. They vary from greenish tinged with yellow to pink, to crimson. The exit hole on the underside of the leaf has a tuft of unicellular hairs, but the interior of the gall is thin walled and lacks hairs.

*Vasates aceriscrumena* is similar to *V. quadripedes*. It is recognized by having two spinules on the anterior lobe of the dorsal shield, by the forward-centrad direction of the dorsal setae, and by the well-pronounced design of the dorsal shield. The life history of both species is similar.

Specimens are found in galls through July on sugar maple in the Eastern United States and Canada. This mite was described in 1883 as *Phytoptus acericola* by Garman, who reported that it caused galls on maple in Illinois. It is a synonym of *V. aceriscrumena*.

References: Garman, *1883: 135;* Hodgkiss, *1930: 21;* Jeppson et al., *1975: 459, 498;* Riley, *1870: 339.*

**Anacardiaceae**

***Rhus diversiloba* Torr. & A. Gray Poison Oak**

***Rhus radicans* L. Poison Ivy**

**Leaf gall caused by *Aculops toxicophagus* (Ewing) (pl. 11)**

Infestation is common and typical of the leaf galls. It consists of puckered, irregular, rounded, or wartlike pouches affecting both upper and lower surfaces of the leaves. The galls are usually scattered about indiscriminately on the leaf blade. They range from green to pinkish, to red brown. Poison oak leaves are often so heavily attacked that they become visibly crinkled and distorted.

*Aculops toxicophagus* is a brownish, slender, spindle-shaped mite. The female measures 145-155 microns long and the male 120-130 microns. The featherclaws are four-rayed; the dorsal shield is slightly produced anteriorly and marked with a design; the microtubercles are larger and more rounded dorsally than ventrally; and the coverflap of the female genitalia has eight to nine longitudinal ribs. Nothing is known of this mite's seasonal history.

Specimens were collected on poison oak in Oregon and California and on poison ivy in Ohio and Maryland. It has also been found on poison sumac (*Rhus vernix* L.) in Ohio. The mite is probably present throughout its host range.

References: Ewing, *1917: 323;* Keifer, *1938a: 191.*

**Betulaceae**

***Alnus oregona*** **Nutt. (= *rubra* Bong.) Oregon Alder, Red Alder**

***Alnus rhombifolia*** **Nutt. White Alder**

***Alnus rugosa*** **(Du Roi) K. Spreng. Hazel Alder**

***Alnus tenuifolia*** **Nutt. Mountain Alder**

**Leaf gall caused by *Phytoptus laevis* Nalepa (pl. 12)**

These beadlike galls are particularly striking because they appear on both surfaces of the leaves. They are small, hemispherical, of variable size and are scattered singly or crowded alongside the midrib. The galls are firmly attached, with the exit holes on the underside. They are shiny externally and the interior contains fleshy tissue. They range from green to yellowish, to red, to reddish brown as they mature. A single leaf may carry numerous galls so that it becomes distorted and its growth inhibited.

*Phytoptus laevis* is a yellowish, wormlike eriophyid, measuring about 190 microns long. The featherclaws are four-rayed; the dorsal shield of the male and female (protogyne) may be marked with ridges; the microtubercles are few and acuminate; those posteriorly on the ventral side are elongate. The overwintering female (deutogyne) has a smooth dorsal shield and fewer microtubercles confined to the ventral side of the hysterosoma; the dorsal setae are directed forward or dorsocentrad; and the coverflap of the female genitalia is smooth and lacks ribs. The life history involves alternation of generations. Although *P. laevis* is a common species on alder, little is known of its seasonal history and habits. Specimens were abundant in August.

The hosts are Oregon or red alder, white alder, and mountain alder in California and hazel alder in Ohio and Georgia.

**Compositae**

***Baccharis pilularis* var. *consanguinea* (D. C.) O. Kuntze**
**Chaparral Broom**

**Leaf gall caused by *Eriophyes baccharipha* (Keifer) (pl. 13)**

This gall is known as *Baccharis* leaf blister, a pimplelike swelling that develops on both sides of the leaf blade, with the exit hole on the underside. Generally an infestation gives the leaf a pimply, blistered appearance. The galls vary in size and from greenish to yellow, to brown.

*Eriophyes baccharipha* is a wormlike, yellowish mite, measuring 165-215 microns long. The featherclaws are six-rayed; the dorsal shield is produced anteriorly and marked with two strong, long, median and a few short, submedian ridges; the microtubercles on the hysterosoma are slightly pointed; and the coverflap of the female genitalia has two rows of ribs. The mites occur among the fleshy tissue in the galls and presumably leave the galls and migrate to the buds during unfavorable weather. Nothing is known of the life cycle of this species.

The host plant is locally known as chaparral broom, a spreading evergreen shrub that occurs in coastal and inland hills in California and southern Oregon. The mite specimens were first collected in California in April. *Eriophyes baccharipha* should not be confused with two other eriophyids that infest *Baccharis* in California. They are *Eriophyes calibaccharis* Keifer, which occurs in the terminal buds of chaparral broom, and *E. baccharices* (Keifer), which causes irregular, wartlike, rough-looking galls on the upper surface of the leaves of seep willow (*Baccharis glutinosa* Pers.) and mule-fat (*B. viminea* D. C.).

**Juglandaceae**

***Juglans californica* S. Wats. California Walnut**

***Juglans hindsii* (Jeps.) Jeps. Hind's Walnut**

**Leaf gall caused by *Eriophyes brachytarsus* Keifer (= *E. amiculus* Keifer and *E. brevitarsus* Keifer) (pl. 14)**

The pouch galls induced by this mite on the upper surface of the leaves invariably appear at random between the lateral veins and on the midrib. The galls are often solitary, 3-6 mm in dimension, irregularly globular, and shiny with roughened surface. They range from green to yellowish green with reddish or brown tinge. The interior of the gall, which becomes red as it matures, consists of multicellular structures, as shown in plate 6, *E.* Galls at times are numerous on some trees, causing considerable distortion to the foliage.

*Eriophyes brachytarsus* is a slender, wormlike mite, measuring 195-210 microns long. The male and female (protogyne) are yellowish, whereas the overwintering female (deutogyne) is reddish. The featherclaws are three-rayed; the dorsal shield has an obscure design; the coverflap of the female genitalia is smooth; the setal bearing tubercles are not produced; and the microtubercles of the protogyne and male are pointed, and those of the overwintering female are simple and rounded. The life history involves alternation of generations (see Jeppson et al. (*1975*)). Overwintering females are found in the terminal buds in late winter and in new galls in April. The males and protogynes appear in May, inhabiting the galls through August. Both forms are found in the galls during this period.

Specimens were collected in the galls on California and Hind's walnuts in California. *Eriophyes brachytarsus* is similar to *E. microcarpae* Keifer, which causes similar pouch galls on little walnut (*Juglans microcarpa* Berland) and Arizona walnut (*J. major* (Torr.) A. Heller) in Texas, New Mexico, and Mexico. *Eriophyes amiculus* was subsequently observed to be the bisexual form (male and protogyne) of *E. brachytarsus* and is therefore a synonym. *Eriophyes brevitarsus* is a preoccupied name.

References: Jeppson et al., *1975: 377, 433;* Johnson and Lyon, *1976: 430, 432;* Keifer, *1939b: 224; 1939c: 328; 1969: 15; 1974: 7.*

**Juglandaceae**

***Juglans nigra* L. Black Walnut**

**Petiole gall caused by *Eriophyes caulis* Cook (pl. 15)**

This is an exceptionally interesting and beautiful pubescent gall, often brightly colored, passing from greenish through pink and crimson to reddish brown. The gall most frequently develops as an irregular, solid, hard mass on the leaf petiole. It is often solitary and variable in size. The exterior is covered with a dense mass of silky, unicellular, erineumlike hairs (see pl. 7, *A*). The gall tends to be large and to spread to and partly envelop the stem and leaf. The affected structure is greatly distorted and twisted, and leaflets fail to develop.

*Eriophyes caulis* is a slender, wormlike mite, measuring 150-210 microns long. Deutogynes, or overwintering females, are reddish. The featherclaws are three-rayed; the dorsal shield has two distinct parallel ridges at the middle; the cover-flap of the female genitalia is smooth; and the microtubercles of the males and protogynes are pointed, and those of the deutogynes are rounded and thickened posteriorly. The life history involves alternation of generations; only the deutogynes overwinter in the buds. Both forms may be found among the dense mass of erineum hairs during the summer.

This mite was found infesting black walnut in New Jersey and Pennsylvania in July-August. It is probably distributed throughout the range of its host from Ontario to Massachusetts and south to Florida and eastern Texas. *Eriophyes caulis* is similar to and may be confused with *E. brachytarsus* Keifer, which causes pouch galls on leaves of California walnut.

References: Cook, *1904: 859;* Jeppson et al., *1975: 434;* Johnson and Lyon, *1976: 430;* Keifer, *1940a: 24.*

**Liliaceae**

***Aloe nobilis* Haw. Golden-Tooth Aloe**

***Aloe spinosissima* Hort. ex A. Berger Spider Aloe**

***Haworthia* sp. Star Cactus, Wart Plant**

**Leaf and inflorescence gall caused by *Eriophyes aloinis* Keifer (pl. 16)**

An affected plant shows a remarkable proliferation of unsightly, irregular outgrowth, clustered densely on the surface of the leaf blades or in leaf axils. The infestation may be confined to the base in the leaf axils as bunched, greenish, tiny-to-large globular sprouts or as a lumpy, rough-looking thickening in the form of wartlike growths from the base of the leaf blade extending to the tip. The longitudinal pattern of growth follows that of the lanceolate shape of the leaf. It ranges from yellowish to brownish, to green tinged with yellow. The mites also attack the inflorescence and cause galled blooms.

*Eriophyes aloinis* is a purplish, slender, wormlike mite, measuring 190-220 microns long. The featherclaws are six-rayed; the dorsal shield is marked with median ridges flanked by branching lines; the microtubercles are elliptical, each with a tiny point; the coxae have fewer granules; and the coverflap of the female genitalia has seven to nine ribs. The mites live in crevices among the various growths and were collected in November.

This eriophyid attacks golden-tooth aloe, spider aloe, and star cactus or wart plant in southern California and Florida. It is probably found wherever these plants are grown.

References: Denmark and Keifer, *1979: 1-2;* Keifer, *1941: 205.*

**Meliaceae**

***Sandoricum koetjape* (Burm. F.) Merr. Santol**

**Leaf gall caused by *Eriophyes sandorici* Nalepa (pl. 17)**

This is an unsightly pouch gall that develops on the underside of the leaf blade as a concavity filled with erineum and on the upper side as a rounded outpocketing with irregular puckered domes. The pouch is greenish, becoming blackish, and the erineum turns brownish at maturity. The galls are variable in size and are frequently coalesced and crowded, giving a lumpy appearance to the leaf blade.

The mite is robust and wormlike, measuring about 180 microns long. The featherclaws are five-rayed; the dorsal shield is marked with a design; the microtubercles are elliptical dorsally, rounded ventrally, and usually anterior to the ring margins; and the coverflap of the female genitalia has long ribs. The life cycle and seasonal distribution are unknown.

*Eriophyes sandorici* has been found only on santol of the mahogany family Meliaceae, a tropical tree with edible fruit from the Indomalayan region and Mauritius.

Reference: Nalepa, *1914: 66.*

**Oleaceae**

***Fraxinus americana* L. White Ash**

***Fraxinus latifolia* Benth. Oregon Ash**

***Fraxinus pennsylvanica* var. *lanceolata* Bork. Green Ash, Red Ash**

**Leaf gall caused by *Eriophyes chondriphora* (Keifer) (pl. 18)**

The galls on the upper surface of ash leaves are unmistakable and often particularly numerous on the terminal leaves. They are small and solitary, somewhat reniform in shape, and generally scattered at random on the lateral veins. Their greenish-yellow color and shape give a striking effect on an infested leaf.

*Eriophyes chondriphora* is a robust, spindle-shaped, yellowish mite, measuring 210-260 microns long; the protogyne female is larger than the deutogyne. The featherclaws are three-rayed; the dorsal shield of the protogyne and male is marked with granules and faint ridges; the hysterosoma is covered with rounded microtubercles, and that of the deutogyne is unmarked and has no microtubercles; and the coverflap of the female genitalia is smooth. The mites inhabit the galls until the leaves mature in late summer. The life history apparently involves alternation of generations.

Specimens were found in galls on leaves of white, Oregon, and green or red ash in California, Wisconsin, Virginia, New York, Vermont, and Canada. In Europe, *Eriophyes fraxinicola* (Nalepa), a closely related species of *E. chondriphora,* makes similar galls on leaves of European ash (*Fraxinus excelsior* L.).

Reference: Keifer, *1965a: 5.*

**Polypodiaceae**

***Pteridium aquilinum* var. *lanuginosum* (Bong.) Fern. and *P. aquilinum* var. *latiusculum* (Desv.) Underwood Bracken**

**Pinnule gall caused by *Phytoptus helicantyx* (Keifer) (pl. 19)**

This is a beautiful marginal roll gall of bracken. When seen under a microscope, it looks like a delicate, pale, lime-green lace border on the underside of the pinnule. The first indication of infestation is a characteristic discoloration and distortion of the pinna. The affected pinna is generally yellowish, later turning brown. The galled pinnules are abnormally small and distorted, with a thickening of reflexed margins. The indusium, which becomes enlarged, contains mites and lime-green erineumlike hairs. The infestation occurs in June-July.

*Phytoptus helicantyx* is a wormlike, yellowish-white mite, measuring 250-320 microns long. The featherclaws are 3-rayed; the dorsal shield is marked with broken lines made up of short dashes and does not project anteriorly over the rostrum; the microtubercles on the hysterosoma are elongate dorsally, becoming pointed ventrally; there are granules on the coxae; and the coverflap of the female genitalia has 11–12 longitudinal ribs. The mites live among the erineum hairs in the gall.

This species was first collected in Massachusetts on bracken (*Pteridium aquilinum* var. *lanuginosum*). It was recently found in Maryland on another variety of bracken (*P. aquilinum* var. *latiusculum*). Keifer (*1966b*) mentioned an undescribed species associated with *Phytoptus helicantyx* that has four-rayed featherclaws. These two species should not be confused with one another. In Europe, *Phytoptus pteridis* Mollard has been described as causing leaf edge roll on bracken, and *Eriophyes pteridis* Nalepa, according to Darlington (*1968*), causes roll gall on bracken somewhat similar to that formed by a gall midge.

References: Darlington, *1968: 113;* Keifer, *1966b: 17.*

**Rhamnaceae**

***Ceanothus velutinus* Dougl. Redroot**

**Leaf gall caused by *Eriophyes ceanothi* Keifer (pl. 20)**

These are unique galls that develop on the underside of leaves. They are small, rounded, solitary, or clustered, and they are scattered haphazardly over the leaf blade and along the leaf margin. Their positions are marked on the upper surface by small, white spots, each with a tiny escape hole. The presence of white spots against the green background of the upper leaf blade makes the galls striking and easily recognizable. The galls are of the same whiteness as the underside of the leaf blade. Frequently the plant is heavily galled. These interesting and beautiful galls are caused by *Eriophyes ceanothi.*

This mite is robust, wormlike, yellow or orange and measures 120–145 microns long. The featherclaws are 5-rayed; the microtubercles on the hysterosoma are elliptical; the dorsal shield has a design formed by granules, and the dorsal setae are directed backward; the coxae have a few minute granules; and the coverflap of the female genitalia has 11 ribs. The mites are found colonizing the galls. Although the galls are abundant on the leaf, most of those examined in July-October did not contain mites.

*Eriophyes ceanothi* occurs on redroot, an evergreen shrub found from British Columbia to Colorado and California. Specimens of mites were first collected in Oregon and subsequently in California.

Reference: Keifer, *1939c: 330.*

**Rosaceae**

***Adenostoma fasciculatum* Hook. & Arn. Greasewood**

**Leaf gall caused by *Phytoptus adenostomae* Keifer (pl. 21)**

This typical pouch gall, which is distinctive and attractive, occurs on a tiny, narrow, elongate leaf blade of a rosaceous plant. The galls are hemispherical with roughened, puckered domes; they are solitary and rarely coalescent. There are seldom more than two pouches on one leaf. Initially the galls are the same color as the rest of the leaf blade, becoming brown as they mature. Infested leaves tend to be those under shady areas or where they are less exposed to sunlight. Heavily infested plants have malformed leaves that are noticeable at a distance.

*Phytoptus adenostomae* is a yellowish-white, wormlike mite, measuring 90-140 microns long. The featherclaws are 4-rayed; the dorsal shield is smooth anteriorly and has 3 short ridges posteriorly between the setal bases; the coxae have fewer granules; and the coverflap of the female genitalia has 10 ribs of uneven length. The microtubercles of the overwintering females (deutogynes) are large and subelliptical; those of the protogynes and males are slightly pointed and smaller. An accessory seta is present. The life history involves alternation of generations.

The host plant is locally known as greasewood, an evergreen shrub of the Rosaceae family; it grows in the chaparral area in California.

Reference: Keifer, *1976: 19.*

PLATE 21.—*A, B,* Galls on greasewood leaves; note large puckered domes on upper surface; *C, Phytoptus adenostomae* Keifer. (DES, deutogyne microtubercles, lateral view; MES, male microtubercles, lateral view.)

**Rosaceae**

***Prunus americana* Marsh. Wild Plum**

***Prunus domestica* L. Common or European Plum**

***Prunus emarginata* (Dougl. ex Hook.) Walp. Bitter Cherry**

***Prunus munsoniana* Wight & Hedr. Wild-Goose Plum**

***Prunus subcordata* Benth. Sierra Plum**

***Prunus virginiana* var. *demissa* (Nutt.) Sarg. Chokecherry**

**Leaf gall caused by *Phytoptus emarginatae* (Keifer) (pl. 22)**

The galls induced by *Phytoptus emarginatae* are familiar and typically pouch type. They are scattered at random over the surface of the leaves. Each gall is elongate, clavate or finger-like, of variable length, and erect or oblique. It protrudes through the upper surface of the blade; occasionally two galls are coalesced. Generally the galls are most conspicuous when yellowish and beginning to turn light brown.

The mite is robust, wormlike, and whitish or yellowish brown; it measures about 240 microns long. The featherclaws are four-rayed; the female dorsal shield has no markings, and the dorsal setae are directed forward or dorsocentrad; the coxae are smooth; there are more ventral than dorsal rings; the microtubercles are absent; also some of the posterior ventral rings have ridges arranged similarly to microtubercles; and the coverflap of the female genitalia lacks ribs. The male differs by having ridges on the dorsal shield and microtubercles on the hysterosoma. It also possesses more rings than the female.

The interesting biology of this mite has been studied by Oldfield (*1969*). The life cycle involves one generation each year. The females overwinter in crevices of old buds near the base of branches and move to newly developing leaves in the spring. *Phytoptus emarginatae* is associated with *P. prunidemissae* (Keifer), which normally inhabits the young buds near the tips of branches and later invades the galls caused by *P. emarginatae*. By late summer the latter species is outnumbered by *P. prunidemissae*.

*Phytoptus emarginatae* appears to be widespread on several species of *Prunus*. It was first collected in galls on bitter cherry in California and subsequently in galls with *Phytoptus prunidemissae* on chokecherry in many areas of the Western United States. Other hosts include wild, common or European, wild-goose, and Sierra plums.

References: Keifer, *1939a: 3, 4;* Oldfield, *1969: 269.*

**Rosaceae**

***Prunus serotina* J. F. Ehrh. Blackcherry**

**Leaf gall caused by *Phytoptus cerasicrumena* Walsh (pl. 23)**

This is a striking and impressive pouchtype gall that appears on the upper surface of the leaf. Each gall is elongate, spindle shaped, about 4-8 mm long, with a pointed or attenuate tip, and is attached to the leaf blade by a slender stalk. The galls are solitary and tend to crowd, often particularly on the basal part of the leaf, mostly near the midrib. They vary from yellowish green to brownish, to reddish. The interior of the gall, where the mites are found, is hollow, with fleshy, turgid tissue. When mature, the galls split open longitudinally, dispersing the mites.

*Phytoptus cerasicrumena* is wormlike and yellowish. The featherclaws are palmate and five-rayed; the dorsal shield of the males and protogynes is marked with a design, and the dorsal setae are short, directed upward; the entire hysterosoma is covered with microtubercles, which are rounded ventrally and elongate dorsally; deutogynes, or overwintering females, lack microtubercles dorsally; and the coverflap of the female genitalia has laterally directed curved ribs. The life history involves alternation of generations. Protogynes and males can be found in the galls during May-June, after which overwintering females appear during July-August. In September no mites are left in the galls.

Specimens have been found only on blackcherry in the Eastern United States. *Phytoptus cerasicrumena* is not likely to be confused with other species that infest *Prunus*. The galls induced by this mite are distinctive.

Reference: Walsh, *1868: 55*.

**Rubiaceae**

*Cephalanthus occidentalis* **L. Buttonbush**

**Leaf gall caused by *Eriophyes cephalanthi* Cook (= *E. newkirki* Keifer) (pl. 24)**

The galls induced by this mite are easily distinguished by their position on the leaves. Either they occur on the lateral veins, or, when numerous, they are haphazardly scattered singly or in clusters on the upper surface of the leaf blade. The galls are small, variable in size, with hemispherical domes widely open on the underside. They range from yellow to yellowish tinged with red or pink, later becoming brown. The outer surface of the gall is covered with short, white hairs, and the interior is filled with erineumlike hairs, some of which project through the wide exit hole. A young leaf may have so many galls that its growth appears to be inhibited.

*Eriophyes cephalanthi* is a robust, spindle-shaped, yellowish-white mite, measuring 163-232 microns long. The featherclaws are 4-rayed; the dorsal shield is marked with parallel ridges, the median being longest, and laterally above the coxae these ridges are interspersed with granules; the microtubercles are elongate and slightly acuminate posteriorly; and the coverflap of the female genitalia has 8–10 short, weak ribs. The life history of this mite is unknown. The mites were found among the hairs in the galls.

The host is buttonbush, a shrub that grows along streams and swamps in the Eastern and Western United States. Specimens were collected in Washington, D.C., and Florida. *Eriophyes newkirki* Keifer is a synonym of *E. cephalanthi.*

References: Cook, *1906: 250;* Keifer, *1973: 1.*

**Salicaceae**

***Populus tremuloides* Michx. Quaking Aspen**

**Leaf gall caused by *Phyllocoptes didelphis* Keifer (pl. 25)**

The mite induces circular, shallow galls, 5-15 mm in diameter, outpocketed from the upper surface of the leaf blade. The underside is open and filled with firm, yellowish, irregular epidermal growth (see pl. 5, *A*). The mites live within the recesses of the growth or partly exposed to the surface, and when disturbed they remain motionless. The infestation seems particularly to affect the lower shaded branches of the tree.

*Phyllocoptes didelphis* is spindle shaped, measures 230-250 microns long, and varies from creamy to reddish depending on age. The featherclaws are 3-rayed; the dorsal shield has a ridge over the anterior lobe and a longitudinal median ridge; the dorsal setae are directed forward; the hysterosomal microtubercles are elongate dorsally and rounded ventrally; the female coverflap has 12–14 ribs; and small accessory setae are present. The life cycle is unknown. Specimens were found in July.

The host is quaking aspen from California. *Aculus dormitor* (Keifer) is an inquiline in the gall.

Reference: Keifer, *1954: 125, 126.*

**Salicaceae**

***Salix* spp. Willow**

**Leaf gall caused by *Aculops tetanothrix* (Nalepa) (pl. 26)**

Various willows are commonly infested by eriophyids. The situation is rather complex because the taxonomy of both the mites and the galls is uncertain. The galls on different willows are usually distinguished by form, color, position, density, and texture. *Aculops tetanothrix* belongs to a complex of gall-forming eriophyid species that induce galls on different willows; consequently, the galls are varied. The galls caused by *A. tetanothrix* are 2–3 mm in diameter, beadlike, and irregularly rounded. They are often coalesced and scattered randomly or clustered alongside the midrib and in between lateral veins on the upper surface of the leaf blade. They vary from yellowish green to pinkish or reddish brown and purple. The exterior of the gall may appear roughened and shiny or covered with fuzzy fine hairs as on pussy willow leaves. Galls may be so numerous that they cover the entire leaf blade.

*Aculops tetanothrix* is a robust, yellowish-to-brownish, spindle-shaped mite, measuring about 190 microns long. The featherclaws are four-rayed; the dorsal shield is produced anteriorly, with a prominent sculptured design; and the cover-flap of the female genitalia is ribbed.

The protogynes and males differ by having microtubercles over the entire hysterosoma, whereas the overwintering females (deutogynes) have microtubercles only ventrally. The life history involves alternation of generations. The mites live in the fleshy interior of the galls, but when the galls become hard, they migrate to bark crevices and lateral buds. Only the secondary females overwinter in the lateral buds.

*Aculops tetanothrix* infests leaves of many willows in California, east to Utah and Arizona, and in the Eastern United States. This mite should not be confused with *A. aenigma* (Walsh), which recently has been found in galled inflorescences of willow in Maryland, Ohio, and Pennsylvania (see pl. 26). *Aculops aenigma* was previously reported from Europe.

References: Jeppson et al., *1975: 331;* Keifer, *1966c: 13;* Nalepa, *1889: 145;* Walsh, *1864: 576.*

**Saxifragaceae**

***Ribes divaricatum* Dougl. Coastal Black Gooseberry**

***Ribes roezlii* Regel Sierra Gooseberry**

**Leaf gall caused by *Eriophyes breakeyi* (Keifer) (pl. 27)**

The infestation caused by this mite results in the formation of peculiar galls involving the midrib and lateral veins of the upper surface of the leaves. The galls consist of pouchlike swellings arising from the leaf surface around the midrib and lateral veins, with the edges meeting over the veins to form "globular chambers." The galls coalesce and are covered with whitish hairs, which make them conspicuous and unmistakable. Galled leaves are considerably deformed.

*Eriophyes breakeyi* is a robust, reddish, wormlike mite, measuring 220–240 microns long. The featherclaws are three-rayed; the dorsal shield is smooth anteriorly, with two median ridges posteriorly; the microtubercles are rounded, covering the entire hysterosoma except the dorsal posterior end; the coverflap of the female genitalia is smooth; and setal tubercles are spurlike.

Specimens were found in the galls on Sierra gooseberry in California and on coastal black gooseberry on Orcas Island, Wash., in September. Nearly every leaf of a plant was reported to be galled.

Reference: Keifer, *1959a: 272.*

**Tiliaceae**

***Tilia* spp. Basswood, Lime Tree, Linden**

**Leaf gall caused by *Phytoptus tiliae* Pagenstecher (pl. 28)**

The nail galls on linden leaves induced by *Phytoptus tiliae* are a familiar and striking foliage injury. They are usually numerous and are scattered at random over the leaf surface, generally missing the veins. Each gall is an elongate structure, attenuate distally, with a rounded or pointed tip, measuring 5–12 mm long, which may be erect, oblique, or curved, protruding through the upper surface of the leaf blade. Sometimes two galls are coalesced at the base but form separate apices. The interior of the gall is filled with long, simple hairs near the base or opening (see pl. 6, *D*). The galls vary from greenish yellow to pinkish, to red and brown. They appear in June, maturing in July-August.

*Phytoptus tiliae* is a slender, wormlike eriophyid, measuring 150–170 microns long. The featherclaws are four-rayed; distinguishing characteristics are dorsal setae directed forward and elliptical microtubercles; the coxae are granular; and the coverflap of the female genitalia has six ribs. Although a common species, nothing is known of its life history. It is one of the many eriophyids that attack the linden family Tiliaceae and cause galls to form.

*Phytoptus tiliae* is apparently widely distributed.

References: Keifer, *1952d: 38;* Pagenstecher, *1857: 46.*

**Ulmaceae**

*Ulmus americana* **L. American Elm**

**Leaf gall caused by *Eriophyes parulmi* (Keifer) and *E. ulmi* (Garman) (pl. 29)**

Two kinds of eriophyid galls are easily recognized on elm leaves. *Eriophyes parulmi* causes small, elongate, fingerlike galls that project from the upper surface of the leaf blade. They are randomly arranged, solitary, rarely coalesced and tend to crowd in the angles between the midrib and lateral veins. Specimens were found in July from Wisconsin westward.

*Eriophyes ulmi* causes the formation of small, variable, beadlike galls on the upper surface of leaves. Their exterior is rough, irregular and is covered with a few hairs like the rest of the leaf surface. They are the least impressive of the two galls. Specimens were collected in Canada and the Eastern United States on American elm and in England and Cyprus on elm.

The mites have typical *Eriophyes* characters. *Eriophyes ulmi* may be readily identified by having two-rayed featherclaws, whereas *E. parulmi* has five-rayed featherclaws. The life history of both species is unknown.

References: Garman, *1883: 137;* Keifer, *1965a: 9.*

## Bud, Inflorescence, and Stem Galls, Brooming, and Rosette

### Anacardiaceae

*Mangifera indica* **L. Mango**

**Bud gall, stunted twigs, and defoliation caused by *Eriophyes mangiferae* (Sayed) (pl. 30)**

Infestation of the buds results in arrested growth, with the stunted, short, young stems close together at the terminal branch. When the leaves fall, the overall effect is scant growth of twiggy bunches, with a few stubby, short branchlets and discolored buds. Young trees are most seriously affected.

*Eriophyes mangiferae* is a wormlike, yellowish mite, measuring up to 225 microns long. The female has six- and the male five-rayed featherclaws; the dorsal shield is marked with a design of strong longitudinal ridges confined to the area between the dorsal tubercles; the more easily recognizable features are the hysterosomal microtubercles, which are elongate dorsally and rounded ventrally; and the coverflap of the female genitalia has longitudinal ribs of two uneven ranks. The mites are found in the buds.

This species was discovered in Egypt on mango. It has been reported in Brazil, Mexico, India, Venezuela, and Florida. *Eriophyes mangiferae* was recently collected on galled inflorescences of mango trees in India. However, it is not known whether this mite causes the injury.

**Betulaceae**

***Corylus avellana* L. Filbert, Hazelnut**

**Big bud or bud gall caused by *Phytocoptella avellanae* (Nalepa) (pl. 31)**

The bud gall, known as big bud, consists of an aggregation of swollen, thickened scale leaves, often containing hundreds of mites. Their feeding activities suppress the developing young leaves or inflorescences enclosed within the scales. Eventually the enlarged buds become dark and reddish brown as they mature.

*Phytocoptella avellanae* is an unusual eriophyid in that it has two pairs of setae on the dorsal shield and a pair of subdorsal setae on the hysterosoma. It is yellowish and wormlike, measuring 220–260 microns long. The featherclaws are asymmetrical, 4- to 5-rayed; the microtubercles are slightly pointed and lacking on the posterior 8–10 rings of the hysterosoma; the coxae are smooth; and the coverflap of the female genitalia lacks ribs. The nymphs are remarkably different from the adults. They are flattened dorsoventrally and found lying along the veins on the underside of the leaves. Adult mites may be found in the buds throughout the summer. Another eriophyid, *Cecidophyopsis vermiformis* (Nalepa), which causes crinkly leaves in Europe and summer big bud in this country, probably also occurs as an inquiline.

The mite infests filbert or hazelnut in this country and in Europe. Another pest of filbert found in Oregon is *Aculus comatus* (Nalepa). Its feeding causes bronzing or russeting on the leaves and leaf edge rolling when the infestation is severe.

References: Keifer, *1940b: 112;* Krantz, *1973: 709;* Nalepa, *1889: 128.*

**Compositae**

***Chondrilla juncea* L. Skeletonweed**

**Bud gall caused by *Eriophyes chondrillae* (Canestrini) (pl. 32)**

Mite infestation of the flower buds inhibits elongation of the flowering stems and lateral branches. There is considerable distortion of the galled structure, which appears cauliflower-like and of variable size or which forms clusters of aborted and contorted lateral branches, foliage, and flower heads. Since the flower stems fail to produce flowers, the reproductive capacity of the plant is greatly reduced.

*Eriophyes chondrillae* is one of the many eriophyids that infest various plants of the family Compositae. The feather-claws are six-rayed; the dorsal shield has distinct forked ridges anterior to each of the dorsal setal bases; the microtubercles are elliptical, but they are lacking dorsally toward the posterior end of the hysterosoma; and the coverflap of the female genitalia has longitudinal ribs. The mites inhabit both the galled structures and buds.

The host is skeletonweed, an introduced plant. It is a serious pest of cereal crops in Australia. Skeletonweed is a rapidly growing perennial and may be found in orchards, vineyards, grainlands, and pasturelands in this country. *Eriophyes chondrillae* was introduced into California as a biological control agent of skeletonweed.

References: Canestrini, *1891: 54;* Fuller, *1966: 20.*

**Compositae**

*Lepidospartum squamatum* **(Gray) Gray**

**Bud gall caused by *Eriophyes lepidosparti* (Keifer) (pl. 33)**

The mites attack the buds and inhibit elongation of the shoot; the result is a visible configuration of the affected structure somewhat similar to a rosette. There is considerable crowding and bunching together of malformed, stunted, thickened shoots and aborted buds with short outgrowths.

This wormlike, pinkish mite measures 170–180 microns long. The featherclaws are 5-rayed; the dorsal shield has numerous short, weak lines scattered at the middle and enclosed by 2 longitudinal, parallel ridges; the hysterosoma is completely covered with rounded microtubercles; the coxae are abundantly granular; and the coverflap of the female genitalia has 14 radiating ribs. This last characteristic is particularly distinctive.

The mites inhabit the buds. They were found in June on *Lepidospartum squamatum*, a rigid broomlike shrub common in washes and gravelly places in California.

Reference: Keifer, *1951: 95.*

**Cupressaceae**

***Juniperus californica* Carr. California Juniper**

***Juniperus occidentalis* Hook. Sierra Juniper**

***Juniperus scopulorum* Sarg. Rocky Mountain Juniper**

***Juniperus virginiana* L. Red Cedar**

**Berry gall and deformed, shriveled berries caused by *Trisetacus batonrougei* Smith, *T. neoquadrisetus* Smith, and *T. quadrisetus* (Thomas) (pl. 34)**

There are a few mites that infest juniper and red cedar berries, transforming them to gall-like structures that contain mites in all stages of development. Five species of *Trisetacus* have now been reported inhabiting Cupressaceae berries or cones in the Holarctic Region (Smith, *1978b*). Three are mentioned here. *Trisetacus quadrisetus* was first collected from berries of common juniper (*Juniperus communis* L.) in Europe. This mite was subsequently reported by Keifer (*1957*) from California and Sierra junipers in California. Smith (*1978a*) described *T. neoquadrisetus* from berries of Rocky Mountain juniper in British Columbia and *T. batonrougei* from red cedar in Ontario. The mites were found in berries that were characteristically deformed, shriveled, and dark. This characteristic injury was described by Morgan and Hedlin (*1960*), who also reported the biology of *T. quadrisetus* infesting Rocky Mountain juniper in British Columbia. Infested berries of junipers in California are shown in plate 34, *A* and *B*.

We did not attempt to diagnose the *Trisetacus* species mentioned here. Smith (*1977*) published a key to the species. For identity of those that infest juniper and cedar berries in North America, we suggest that specimens should be sent to specialists for proper determination. The characteristic symptoms of injury by each *Trisetacus* species appear similar to one another.

**Gramineae**

*Cynodon dactylon* **(L.) Pers. Bermuda Grass**

**Leaf sheath and stem gall caused by *Eriophyes cynodoniensis* (Sayed) (= *Aceria neocynodonis* Keifer) (pl. 35)**

Infested grass exhibits a rosette symptom. Mite feeding apparently inhibits plant growth, in which the leaf sheaths become swollen, closely packed, thickened, and bunched at the stem node, and the leaf blades become stunted. Affected stems have greatly deformed and enlarged nodes and shortened internodes. The infestation showing the characteristic injury becomes evident in the spring on Bermuda grass in lawns and on golf courses; browning and thinning out of the grass follow.

*Eriophyes cynodoniensis* is a slender, wormlike, yellowish mite, measuring 170–210 microns long. The female has 6- and the male 5-rayed featherclaws; the dorsal shield is marked with a distinctive design of 2 scalloped, parallel ridges running the full length of the shield, with a straight, short ridge in between; the microtubercles are elliptical; and the coverflap of the female genitalia has 11–12 ribs, with the median ribs twice as long as the lateral ones. The mites feed and seek shelter in the leaf sheaths. They vary from a few to a hundred or more in a single sheath. They are less abundant in lawns where flood irrigation is used.

Previously this mite was known in Arizona, Georgia, California, and Florida as *Aceria neocynodonis,* a synonym of *E. cynodoniensis,* which was found on grass in Egypt.

**Juglandaceae**

***Juglans hindsii* (Jeps.) Jeps. Hind's Walnut**

**Catkin gall caused by *Eriophyes spermaphaga* Keifer (pl. 36)**

The mites infest almost every male flower in the drooping catkins. There is considerable malformation with excessive development of individual flowers, each resembling a miniature cauliflower head. Galled catkins on a tree are conspicuous from the ground as a green or dirty brown, blackish, lumpy mass. They begin to deteriorate in July, becoming heavily infested by the mildew fungus. Infested catkins often remain attached to the tree so that galls can be seen throughout the season. The mites seem to have the effect of prolonging the life of the catkin. Although female flowers are heavily infested with mites, they do not show signs of malformation. Infestations vary at two localities in California, with great numbers of galled male catkins observed developing on walnut trees at the type locality.

*Eriophyes spermaphaga* is a slender, yellowish-white, wormlike mite. The protogyne and deutogyne females measure 180–220 microns long; the male is about 188 microns long. The featherclaws are three-rayed; the dorsal shield is almost devoid of markings; there are short weak lines between the dorsal tubercles and above the second coxae; the dorsal setae are directed backward and divergent; the coxae and sternal areas are smooth; the microtubercles of the protogyne and male are pointed, and those of the deutogyne are not; the coverflap of the female genitalia is faintly marked posteriorly; and the setal bearing tubercles are produced, constricted, and pointed posteriorly. The male, protogyne, and deutogyne were found inhabiting galled male catkins and female flowers during June-July. The life cycle of this mite has not been observed.

*Eriophyes spermaphaga* was recently discovered on catkins of Hind's walnut from California. No collection has been made in other areas.

This species should not be confused with *Eriophyes neobeevori* Keifer, which causes similar injury to catkins in California walnut (*Juglans californica* S. Wats.) in southern California.

**Oleaceae**

***Fraxinus* sp. Ash**

**Inflorescence gall caused by *Eriophyes fraxinivorus* Nalepa (pl. 37)**

This is an interesting and distinctive gall. The infested inflorescence shows swollen and fused pedicels of individual flowers, often involving the peduncle or stalk. There is considerable distortion, and when the infestation is severe, every inflorescence is galled. Fully developed galls are conspicuously brownish, lumpy, and unsightly, usually remaining attached to the twigs from one season to the next. Galled inflorescences can be found throughout the year and are locally abundant.

*Eriophyes fraxinivorus,* a widespread European species, may be recognized by its four-rayed featherclaws and smooth dorsal shield with a short median ridge posteriorly. Specimens have been collected on galled inflorescences of an unidentified ash from New York and on Oregon ash (*Fraxinus latifolia* Benth.) in California.

Reference: Nalepa, *1909: 117.*

**Rosette galls, stunted needles, and aborted buds caused by *Trisetacus alborum* Keifer, *T. campnodus* Keifer & Saunders, *T. floridanus* Keifer, *T. gemmavitians* Styer, Nielsen, & Balderston, and *T. pseudotsugae* Keifer (pl. 38)**

Several species of *Trisetacus* mites infest conifers. Some of the symptoms of injury caused by these five species are shown in plate 38. Rosette or clustering of numerous aborted buds and stunted needles is the typical injury. Because of the similarity of the injuries on various pines, the taxonomy becomes complex. Distinction of the injury may be based on the part of the plant attacked and on accurate identification of the mites by a specialist.

*Trisetacus gemmavitians* and *T. campnodus* attack Scotch pine. The former mite causes a peculiar gall, which essentially is a conspicuous, beautiful rosette easily seen on pine trees. Each rosette consists of a cluster of aborted buds or stunted needles. Typically the shoots become infested, and the elongation of the growing point is inhibited. Numerous buds are clustered at the tip, and the needles that develop from these buds are stunted. When rosettes are numerous, the value of cut pine trees is greatly reduced. Infestations occur at the base of the needle beneath the sheath. The mites have been collected in the sheaths of stunted needles and in new buds. *Trisetacus gemmavitians* has been reported from Ohio and California.

*Trisetacus campnodus* causes yellowing and stunting of Scotch pine needles. The mites colonize the needle base beneath the sheath. This area becomes necrotic and brown, at times calloused, and eventually the needles turn yellow and stunted, often distorted. Infested pine trees are chlorotic and generally appear unthrifty. This mite species was collected in Washington State.

The injuries on other conifers caused by the following species of *Trisetacus* are not unlike the rosette gall on Scotch pine. *Trisetacus floridanus* has been reported attacking terminal shoots and causing galls, aborted buds, and stunted needles on four species of pines in Florida: Sand, slash, and cedar pines and an unidentified pine species. Specimens have been collected in growing terminal shoots from January through August. *Trisetacus alborum* at times causes the formation of clusters of stunted needles on sugar and western white pines in California. Similar injury is caused on Douglas fir by *T. pseudotsugae*. The mites were found in Oregon infesting nursery seedlings, in which the growing tips form clusters of aborted needles. The infested seedlings are stunted and deformed.

*Trisetacus* mites are distinctive in having three setae on the dorsal shield; all are directed forward. The featherclaws vary from seven to nine rays and the body from 280 to 410 microns long; and the coverflap of the female genitalia is smooth. The species mentioned here share many similar morphological characters that make specific identification difficult. They may be separated, however, by the type of microtubercles on the hysterosoma and by the design on the dorsal shield.

**Rosaceae**

*Prunus domestica* **L. Plum**

*Prunus dulcis* **var.** *dulcis* **(Mill.) D. A. Webb Almond**

**Bud gall caused by** *Acalitus phloeocoptes* **(Nalepa)**

This is an interesting example of a rosaceous bud galled by an *Acalitus* mite. Unfortunately we have no color photograph to illustrate the injury. *Acalitus phloeocoptes* causes permanent irregular galls of various sizes around the buds and deforms the fruit of almond. Infested trees fail to form fruit buds and lose vigor, and the damage appears to be progressive and irreversible. This results in the trees dying in 3 to 6 years. On plum, the mites form small, irregular, subspherical galls, 1.3–1.8 mm in diameter, surrounding the buds and also deforming the fruit. The galls may appear singly or clustered around the buds and become woody. Unlike almond, infested plum trees often recover from mite attack and do not show permanent injury.

*Acalitus phloeocoptes* is wormlike and whitish, measuring 135–150 microns long. The overwintering females are more slender than the mites during the summer. This mite can be easily separated from other species of *Acalitus* by its five-rayed featherclaws, smooth dorsal shield, strong sternal and coxal apodemes, and granular coverflap of the female genitalia. Details of the life cycle are summarized in Jeppson et al. (*1975*). The females overwinter in the hardened galls. When the galls crack in early spring, the mites migrate to newly developing buds.

This mite is distributed throughout southern and central Europe on almond and plum. It has been found in the Eastern United States on the same host plants.

References: Jeppson et al., *1975: 468;* Nalepa, *1926: 80.*

**Rosaceae**

*Spiraea densiflora* **Nutt. ex Rydb. Bridal-Wreath**

**Inflorescence gall caused by** *Phytoptus paraspiraeae* **Keifer (pl. 39)**

The umbellike inflorescence of infested bridal-wreath plants has oval or pear-shaped, greenish and whitish, unopened buds in a cluster of red flowers. Feeding activities of the mites abort the growth of flower buds, preventing the sepals and petals from opening, and the stamens, pistils, and other floral parts are distorted. These galls are induced by *Phytoptus paraspiraeae.*

This mite is robust, wormlike, and yellowish white; the female measures 155–175 microns long and the male 130 microns. The featherclaws are 6-rayed; the surface of the dorsal shield is rough, with numerous short, broken ridges; the dorsal setae are directed forward; the microtubercles are rounded and widely spaced on the rings; the coxae have few granules; and the coverflap of the female genitalia has 10 ribs.

The mites in the galled flower buds were found in California at 1,800 meters in August. The host plant, bridal-wreath, is found from California to British Columbia. In Europe, a closely related species, *Phytoptus spiraeae* Nalepa, also causes similar galls in *Spiraea* flowers.

Reference: Keifer, *1977: 17.*

**Salicaceae**

***Populus fremontii* S. Wats. Fremont Cottonwood**

***Populus* sp. Poplar**

**Catkin gall probably caused by *Eriophyes neoessigi* Keifer (pl. 40)**

The mites colonize catkin flowers, which become enlarged, malformed, and bunched tightly together. The affected floral parts are wrinkled and curled, often containing numerous mites. The elongate, pendulous catkin hangs like a bunch of grapes, its diameter varying from 7.6 to 12.7 cm and length from 15.2 to 25.4 cm. Unlike normal catkins that drop in the spring, infested catkins hang until summer.

It is not certain that *Eriophyes neoessigi* causes the injury. A similar situation is also found on catkins of willow (*Salix*) in Europe (Rack, *1958;* Westphal, *1977*). According to Westphal (*1977*), "Wirrzope" or catkin galls of *Salix* are not induced by eriophyid mites. The pathological tissues have been found to contain bacilliform particles resembling rhabdoviruses and suggesting a viral origin of catkin galls.

*Eriophyes neoessigi* is a slender, wormlike, yellowish mite, measuring 170–200 microns long. The featherclaws are 6-rayed; the distinctive dorsal shield design consists of 3 longitudinal median ridges flanked by 2 pairs of short curved ridges; the microtubercles are elliptical; the coxae are heavily granular; and the coverflap of the female genitalia has 10 ribs in a single row. This mite has a simple life cycle, with reproduction taking place in the infested catkin. It overwinters in the buds, becoming active in the following spring.

Specimens of *E. neoessigi* were first collected on malformed catkins of an unknown poplar in Utah and subsequently on Fremont cottonwood in California. Wilson and Oldfield (*1966*) reported *E. neoessigi* "producing large pendant gall of fasciated outgrowths on staminate catkins of *Populus fremontii* and *P. tremuloides* Michx., quaking aspen." They also listed *Aceria populinquis* Keifer as an inquiline in galls infested by *E. neoessigi* on Fremont cottonwood.

References: Jeppson et al., *1975: 362;* Keifer, *1940a: 22;* Rack, *1958: 31;* Westphal, *1977: 193;* Wilson and Oldfield, *1966: 590.*

**Salicaceae**

***Populus* sp. Poplar**

**Bud gall caused by *Eriophyes parapopuli* Keifer (pl. 41)**

The gall-induced *Eriophyes parapopuli* consists of an irregular, asymmetrical, solid mass of fleshy swelling. It usually develops on one side of the stem, ringing the base of a developing bud or shoot. The rapid proliferation of the fleshy tissue makes the gall appear lumpy and tuberculated. It is brown tinged with greenish and whitish powdery material. Its dimensions vary considerably since it continues to grow and enlarge. Old galls may persist and be found at any season.

This eriophyid is robust, spindle shaped, and reddish, measuring about 180 microns long. The featherclaws are 4-rayed; the dorsal shield has an obscure design that forms 2 cells posteriorly between the setal bases; the hysterosoma is covered with rounded, well-spaced microtubercles except the last 10–12 dorsal rings posteriorly; the coxae and the coverflap of the female genitalia are smooth; and accessory setae are present. The mites were collected in January when the galls were about 1.3 cm in diameter. The life cycle is unknown.

*Eriophyes parapopuli* was collected on unknown species of poplar in Montana and California.

Reference: Keifer, *1940a: 22.*

**Taxodiaceae**

***Sequoia sempervirens* (D. Don) Endl. Redwood**

**Bud and terminal shoot injury caused by *Trisetacus sequoiae* Keifer (pl. 42)**

Although this mite is confined locally to California and is perhaps uncommon, it is included here because its host is a well-known conifer. It colonizes and damages the buds, causing browning of the scales and some of the leaves behind the growing point and preventing further growth of lateral buds. As long as the buds or terminal shoots are infested, no new growth develops.

*Trisetacus sequoiae* is a slender, yellowish-white mite; the female measures 205–225 microns long and the male 180 microns. This species is distinguished from other members of the genus by having eight-rayed featherclaws; the dorsal shield has no defined markings, but it has a median indentation posteriorly; the microtubercles are rounded and dense, with fewer dorsally toward the posterior end of the hysterosoma; and the coverflap of the female genitalia, as in other members of the genus, is smooth.

Specimens were collected in buds of redwood during September along the northern California coast.

References: Jeppson et al., *1975: 403;* Keifer, *1970: 2.*

**Ulmaceae**

***Celtis occidentalis* L. Hackberry**

**Bud gall and witches'-broom caused by *Eriophyes celtis* Kendall (= *Aceria snetsingeri* Keifer) (pl. 43)**

Witches'-broom is the most conspicuous symptom of tree injury and is used by laymen to identify hackberry trees. *Eriophyes celtis* causes the brooms on this tree. Infestation of the buds prevents normal growth, and as a result numerous buds are clustered together on the side of the stem. Eventually the buds develop and produce thin, short, stunted, and tightly bunched twigs. The twigs bear large buds with open scales and tend to dieback after a year's growth. Usually the brooms are numerous and contribute to the undesirability of hackberry as a shade tree.

A powdery mildew, *Sphaerotheca phytoptophila* Kellerm. & Swingle (Erysiphaceae), was found intimately associated with the mites. It occurs only on hackberry that has been attacked by the mites, and it thrives on the infested branches or distortions caused by the mites (Salmon, *1900*). This symbiotic relationship between the two organisms was also suggested by L. R. Batra (plant pathologist, U.S. Dept. Agr., Beltsville, Md.). In England, witches'-broom (trunk or branch galls) on birch trees (*Betula*) is induced by fungi belonging to three genera: *Taphrina, Puccinia,* and *Melampsorella.* Another mite, *Eriophyes rudis* (Canestrini), frequently occurs in large numbers as an inquiline in the galls (Darlington, *1968*).

*Eriophyes celtis* is a wormlike mite, measuring about 200 microns long. The featherclaws are five-rayed; the dorsal shield is unmarked except for a short median ridge posteriorly; the microtubercles are irregular and somewhat thickened posteriorly; and the coverflap of the female genitalia is smooth. Little is known of the life history. Eggs are laid in May and colonies develop throughout the spring, summer, and fall. The mites are found in large numbers in the buds, 2,000 or more per bud.

*Eriophyes celtis* has been found on *Celtis occidentalis,* locally known as hackberry, in Ohio, Illinois, and Mississippi. It probably occurs throughout its host range from Quebec to North Carolina and Alabama. *Aceria snetsingeri* Keifer from Illinois is a synonym.

References: Keifer, *1957: 244;* Kendall, *1929: 296;* Snetsinger and Himelick, *1957: 541.*

## Erineum

### Aceraceae

*Acer glabrum* Torr. **Rocky Mountain Maple**

**Erineum caused by *Eriophyes calaceris* (Keifer) (pl. 44)**

This is a colorful and impressive erineum on maple leaves caused by *Eriophyes calaceris* in the Western United States. The erineum growth is pustulelike, consisting of a brightly colored aggregation of tiny papillae. Each papilla is filled with colored fluid, and when magnified it has a rounded or capitate tip. The erineum appears on the upper surface of the leaf and is thickest from the apical half to the edge of the blade, missing the larger veins. It ranges from greenish yellow to pink, crimson, and purplish red. The infestation may be widespread on some trees.

*Eriophyes calaceris* is a robust, wormlike, yellowish mite, measuring 180–190 microns long. The featherclaws are 4-rayed; the dorsal shield is unmarked and smooth; and the coverflap of the female genitalia has 8–10 longitudinal ribs. The males and protogynes possess microtubercles over the entire hysterosoma, whereas the overwintering females, or deutogynes, have microtubercles confined ventrally. The life history involves alternation of generations. The mites continue to colonize the erineum until September and then migrate to stems or twigs and bark crevices. Deutogynes overwinter in bark crevices and then move to newly developing buds in the spring. The inquiline eriophyids *Aculops glabri* (Keifer) and *A. paraglabri* (Keifer) are frequently in the erineum. *Aculops paraglabri* was recently found to be the overwintering form (deutogyne) of *A. glabri* and is therefore a synonym.

This mite was found abundant on Rocky Mountain maple in September in California. It is probably generally distributed throughout the range of the host plant from Alaska to California and east to South Dakota and New Mexico. *Eriophyes calaceris* may be confused with *E. elongatus* Hodgkiss, which commonly infests sugar maple (*Acer saccharum* Marsh.) in the Eastern United States. In addition to the differences in morphological structures, the erineum growths caused by each species are distinguished by their position, form, color, and density.

References: Jeppson et al., *1975: 376;* Keifer, *1952a: 33, 34.*

PLATE 44.—*A,* Erineum on Rocky Mountain maple leaves; *B,* patches of erineum on upper surface of leaf; *C,* *Eriophyes calaceris* (Keifer).

C

**Aceraceae**

***Acer saccharum* Marsh. Sugar Maple**

**Erineum caused by *Eriophyes elongatus* Hodgkiss (= *E. regulus* Hodgkiss) (pl. 45)**

Hodgkiss (*1913*) distinguished *Eriophyes elongatus* and *E. regulus,* which cause the familiar glossy crimson erineum on the leaves of sugar maple. According to Jeppson et al. (*1975*), the latter mite species is a synonym of *E. elongatus.* The colorful erineum on sugar maple is remarkably similar to that produced by *Eriophyes calaceris* (Keifer) on Rocky Mountain maple (*Acer glabrum* Torr.). It is one of the most attractive and brilliant growths on the leaf surface. The pustulelike patches, at first greenish white and later becoming crimson or purplish, are generally scattered on the upper surface of the leaves. Close examination of the erineum patch shows an aggregation of tiny, rounded, capitate papillae that contain red fluid. The density of the erineum is variable. Occasionally the growth becomes extremely abundant and causes leaf distortion and premature leaf drop.

*Eriophyes elongatus* is a slender, yellowish, wormlike mite, measuring 150–216 microns long. The featherclaws are 4-rayed; the dorsal shield is almost unmarked except for an inverted V anterior to each of the dorsal setal bases; the hysterosoma of the overwintering female lacks microtubercles dorsally but has more rings ventrally; the male and protogyne are distinguished by the irregularly placed, coarse, rounded microtubercles of the hysterosoma; and the coverflap of the female genitalia has 10 longitudinal ribs. The life history involves alternation of generations. The mite population reaches its peak in the summer, when the erineum growth is most noticeable and abundant.

Specimens are common on sugar maple in the Eastern United States and Canada. In New York, Hodgkiss (*1930*) reported an uncommon greenish erineum on the underside of sugar maple leaves caused by *Eriophyes modestus* Hodgkiss. The erineum later changes to brownish or blackish. *Aculops maculatus* (Hodgkiss) occurs as an inquiline in the crimson erineum or as a leaf vagrant.

References: Hodgkiss, *1913: 421; 1930: 25, 29;* Jeppson et al., *1975: 457, 459.*

**Annonaceae**

*Annona muricata* **L. Soursop**

**Erineum caused by *Eriophyes annonae* Keifer (pl. 46)**

The erineum on the leaves of soursop may be so widespread on the tree that nearly every leaf is affected. The leaves fail to develop normally, and distortion and stunting are considerable. The position of the erineum on the leaf is interesting. It develops as thick, irregular ridges or strips of tufted hairs on the underside, lying in a ropelike pattern along the midrib, and it may extend beyond the midrib to include the bases of lateral veins. Small blotches of tufts may be seen scattered on the leaf blade. Swellings may appear in the same position on the upper side of the leaf blade. In the early stages of development the hairs are whitish, later turning brownish.

*Eriophyes annonae* is a yellowish-white, wormlike, slender mite, measuring 165–185 microns long. The featherclaws are four-rayed; the dorsal shield has a series of short ridges scattered over the dorsum; the hysterosoma is completely covered with rounded or elliptical microtubercles; the coxae are minutely granular; the coverflap of the female genitalia has two rows of ribs; and the setal tubercles are large and rounded.

*Eriophyes annonae* is a neotropical species. Specimens were found among the erineum hairs in March–July on soursop in Venezuela.

Reference: Keifer, *1973: 3.*

**Fagaceae**

***Fagus grandifolia* J. F. Ehrh. American Beech**

**Erineum caused by *Acalitus fagerinea* (Keifer) (pl. 47)**

The yellow, common, attractive erineum patches on the leaves of American beech occur in the angles between the midrib and lateral veins on the upper surface of the leaf. They are regularly arranged, lying alternately, and extending from the petiole to near the apex of the blade. A few patches may occur between the lateral veins near the leaf margin. The erineum consists of thick, felty hairs, which are pale green in the early stages of development, later turning yellow and brownish. The patches are most noticeable at the yellow stage. Under high magnification, the tip of each erineum hair is lobed or compound capitate. This type of erineum is caused by *Acalitus fagerinea.*

The mite is yellowish and wormlike, measuring 220–250 microns long. The featherclaws are four-rayed; the tibia of leg I lacks seta; the dorsal shield has parallel median and submedian ridges interspersed with granules; the microtubercles are rounded and well spaced; and the coverflap of the female genitalia lacks ribs. In late summer when the erineum starts to dry, the mites migrate to the buds. They overwinter in the buds, becoming active in the following spring.

*Acalitus fagerinea* was first collected in July on American beech in Pennsylvania. It is probably present throughout much of the Eastern United States.

References: Jeppson et al., *1975: 367;* Johnson and Lyon, *1976: 428;* Keifer, *1959b: 650.*

**Fagaceae**

***Quercus agrifolia* Née California Live Oak**

**Erineum caused by *Eriophyes mackiei* Keifer (pl. 48)**

*Eriophyes mackiei* infests California live oak and causes shallow pockets or concavities filled with dense erineum on the underside of the leaves. The erineum pockets appear singly and scattered at random over the leaf blade, generally missing the veins. On the upper surface, the erineum growth is noticeable at first as a green, glossy, rounded swelling, later becoming brown.

The mite is whitish or yellowish, slender, and wormlike, measuring about 230 microns long. The featherclaws are three-rayed; the dorsal shield is marked with a design of two ridges flanked anteriorly and diagonally by short, wavy ridges; the microtubercles are rounded, each with a tiny spine; the coxae are smooth; and the coverflap of the female genitalia has about eight weak longitudinal ribs. Specimens were collected from erinuem pockets in June.

*Eriophyes mackiei* is known only from California. Similar erineum growths on several evergreen oaks (*Quercus*), also in California, are most probably caused by this mite. In the Eastern United States, white oak (*Q. alba* L.) is infested by *Eriophyes triplacis* (Keifer), which causes similarly shallow erineum pockets on the leaves. A closely related species of *E. mackiei, Eriophyes paramackiei* Keifer, also infests California live oak and causes a broom effect of densely clustered, stunted twigs on one side of the stem. The twiggy bunches are stubby, with short, somewhat thickened branchlets, each crowded with numerous buds that contain mites. The tree infested with *E. paramackiei* shows the broom growths at the lower level of the tree, whereas the upper section does not look thrifty.

References: Jeppson et al., *1975: 366;* Keifer, *1938b: 302; 1941: 204.*

**Juglandaceae**

***Juglans cinerea* L. Butternut**

**Erineum caused by *Eriophyes cinereae* Keifer (pl. 49)**

Leaves of butternut are often seen with large patches of erineum, similar in general appearance to that caused by *Eriophyes erineus* (Nalepa) on leaves of English walnut (*Juglans regia* L.). The erineum growths are conspicuous on the underside of the leaf blade, consisting of coalesced patches of dense felted hairs lying alongside the midrib, usually filling the area between the lateral veins. On the upper side, the leaf blade with erineum patches appears swollen and puckered. The growth ranges from light brown to reddish brown.

*Eriophyes cinereae* is morphologically similar to *E. erineus*. It is yellowish, slender, and wormlike, measuring 140–240 microns long. The featherclaws are three-rayed; the dorsal shield is unmarked and smooth; the microtubercles are rounded or subtriangular, and the coxae are smooth; and the female genitalia have a smooth coverflap and strongly produced setal bearing tubercles.

Specimens were collected in New York among erineum hairs on heavily infested butternut leaves. The mite's distribution range is probably that of the host, extending from New Brunswick to Arkansas.

Reference: Keifer, *1940a: 23.*

**Juglandaceae**

***Juglans regia* L. English Walnut**

**Erineum caused by *Eriophyes erineus* (Nalepa) (pl. 50)**

The infestation caused by this mite is most noticeable as shiny, convex swellings on the upper surface of the leaf blade and on the underside as patches of shallow, large, solitary concavities lined with felty, yellowish hairs, among which the mites are to be found. These patches have well-defined edges and lie to the side of the midrib between the lateral veins; the erineum growths miss the small secondary veins and appear as thickened partitions. The erineum is particularly characteristic in that each structure is covered with short, minute, unicellular hairs (see pl. 7, *C*). Although erineum patches are fewer on the leaves, they are easily recognized because of their size and color.

*Eriophyes erineus* is a yellowish-white, slender, wormlike mite, measuring about 225 microns long. The featherclaws are three-rayed; the dorsal shield is smooth anteriorly, with two short ridges posteriorly; the microtubercles are elongate; the coverflap of the female genitalia is smooth; and the setal bearing tubercles are produced and have rounded apices. Unlike other walnut-infesting eriophyids, this mite has a simple life history. During the summer the females migrate from the erineum to the terminal buds, where they overwinter. It is not uncommon to find mites in both the buds and the erineum in the fall.

*Eriophyes erineus* was found on English walnut in California. In Europe and the Near East, this walnut is infested by *Eriophyes tristriatus* (Nalepa), which causes similar erineum galls on the leaves.

References: Jeppson et al., *1975: 434;* Keifer, *1938a: 184;* Nalepa, *1891: 875, 884.*

**Sapindaceae**

***Litchi chinensis* Sonn. Litchi, Lychee**

**Erineum caused by *Eriophyes litchii* Keifer (pl. 51)**

The felty patches of erineum are usually extensive and numerous on a plant and are easily found on the underside of the leaves. They are noticeable as pale-green, convex swellings on the upper side. The erineum in the early stages of development is yellowish, later turning red to dark brown, when it is then most conspicuous. The affected leaves eventually become distorted or curled. For erineum structure, see plate 7, *D*.

*Eriophyes litchii* is a robust, yellowish-to-reddish, wormlike mite; the female measures 110–135 microns long. The featherclaws are 5-rayed; the dorsal shield is marked with a design of various ridges; the coxae have large granules; the hysterosoma is completely covered with elliptical microtubercles; and the coverflap of the female genitalia has about 16 longitudinal ribs filling most of the area. This last feature would readily identify the mite.

The mites inhabit the erineum, and specimens were collected in November on litchi in Hawaii and recently in Canton, China. Litchi or lychee is widely grown in Southeast Asia and elsewhere in the Tropics and Subtropics for its edible fresh and dried fruit.

References: Keifer, *1943: 212;* Nishida and Holdaway, *1955: 1*.

**Vitaceae**

***Vitis* spp. Grape**

**Erineum and deformation of bud clusters and leaves caused by *Colomerus vitis* (Pagenstecher) (pl. 52)**

Three forms of *Colomerus vitis* have been reported to cause different types of injury to grapevines. One form feeds on the leaves and causes the appearance of patches of felty erineum on the lower surface, followed by blisterlike swellings on the upper surface. The erineum patches are whitish at first, then yellow, and finally reddish brown. At times they are abundant in early spring in commercial vineyards or throughout the season on abandoned and backyard vines. Another form of *C. vitis* attacks grape buds, causing such injury as deformation of the primordial bud clusters, distortion of the basal leaves, stunting of the main growing point, and often death of the overwintering buds. This form does not produce erineum on the leaves. The third form produces leaf curl and abnormal plant hairs at the colony sites. For further discussion of the mite injuries on grapes, refer to Jeppson et al. (*1975*).

*Colomerus vitis* is a yellowish, slender, wormlike mite, measuring 160–200 microns long. The featherclaws are five-rayed; the dorsal shield has numerous longitudinal ridges, an ocellar spot near the lateral shield angle, and the dorsal setae are directed forward; the microtubercles are elliptical; and the coverflap of the female genitalia has two rows of ribs. The mites live among the erineum hairs and feed on the lower leaf epidermis between the hairs. Adults overwinter in bud scales on dormant buds, and as soon as the buds open in the spring, the mites migrate to the unfolding leaves. Literature on the biology and habits of this mite is extensive; a summary is given in Jeppson et al. (*1975*).

*Colomerus vitis* attacks various species and hybrids of grapes and is probably widespread. It should not be confused with *Calepitrimerus vitis* (Nalepa), another pest of grapevines (see Jeppson et al. (*1975*)).

References: Jeppson et al., *1975: 415;* Keifer, *1944: 21;* Kido and Stafford, *1955: 119;* Pagenstecher, *1857: 46;* Smith and Stafford, *1948: 317.*

## Fruit and Leaf Discoloration, Russeting, Bronzing, Fruit Hardening, Foliage Withering, and Fruit and Bud Drop

### Palmae

*Cocos nucifera* L. **Coconut**

**Flower and fruit injury and premature fruit drop caused by *Eriophyes guerreronis* (Keifer) (pl. 53)**

This tropical mite injury is an interesting and a serious malady of coconuts. An infestation of female flowers results in hardening and drying of the surface of developing fruit. The injury begins around the floral bracts and extends down to the inner husks or fibers. The injured area becomes shriveled, brown, and scattered. Colonization is at times so dense as to cause considerable damage to infested fruit, and fruit drop may occur.

*Eriophyes guerreronis* is a slender, yellowish, wormlike mite, measuring 205–255 microns long. The featherclaws are 6-rayed; the dorsal shield is marked with longitudinal ridges; the microtubercles are much more elongate dorsally than ventrally; and the coverflap of the female genitalia has 9–12 longitudinal ribs.

The mites were found in coconut flowers and developing fruit in March in Mexico. Additional specimens were collected in Venezuela, Brazil, and West Africa. At times *E. guerreronis* is a serious pest of coconuts.

References: Jeppson et al., *1975: 447;* Keifer, *1965b: 7.*

**Palmae**

***Elaeis guineensis* Jacq. African Oil Palm**

**Leaf blade speckling and black and yellow leaves caused by *Retracrus elaeis* Keifer (pl. 54)**

Leaf discoloration caused by *Retracrus elaeis* represents a spectacular reaction of the plant to mite feeding. This discoloration forms a remarkable contrast on the fronds of the African oil palm. Many small dark spots first appear, speckling most of the leaf blade. Later, affected fronds become black and spotted with yellow and orange and completely yellow and orange with age. Colonization may be so dense as to cause extensive discoloration and loss of chlorophyll.

*Retracrus elaeis* is particularly easy to recognize. The body is white with wax, spindle shaped, somewhat flattened dorsoventrally, and broadest anteriorly; it measures about 160 microns long. The featherclaws are forked or divided, with a small two-rayed lobe arising at the middle; the dorsal shield has five small pointed lobes on each side; in addition to the dorsal setae, a pair of anterior setae is present; both pairs of setae are borne on elongate, bulbous tubercles; the hysterosoma has broad dorsal rings and lacks microtubercles; the ventral rings are narrow; and the coverflap of the female genitalia has a row of short longitudinal ridges confined to the base. The mites are leaf vagrants.

The host is the African oil palm, which is cultivated extensively on plantations in the Tropics for palm oil. *Retracrus elaeis* was found in Colombia, South America, in June.

Reference: Keifer, *1975: 3.*

**Rosaceae**

***Prunus dulcis* var. *dulcis* (Mill.) D. A. Webb Almond**

***Prunus persica* (L.) Batsch Peach**

***Prunus persica* var. *nucipersica* (Suckow) C. K. Schneid. Nectarine**

**Leaf silvering and yellow spot caused by *Aculus cornutus* (Banks) (pl. 55)**

Feeding of the peach silver mite, *Aculus cornutus,* produces the well-known silvering of peach foliage that develops late in the season just before the leaves drop. Another result of the mite's feeding has been termed "yellow spot," which is characterized by yellow spotting and chlorosis alongside the veins, accompanied by upward longitudinal folding of the leaf margin into a troughlike structure. The spots range from pinpoint to more than a millimeter in diameter and are usually circular. In severe infestations, spots coalesce, producing a mottled effect. Transverse sections of affected areas of the leaf blade show disorganization of cell contents and hypertrophy of parenchyma cells. Spots and chlorosis alongside the veins appear to be the result of mite infestation of very young leaves. Mature leaves are not affected by yellow spot. For detailed information, see Wilson and Cochran (*1952*).

*Aculus cornutus* is a robust, light amber or yellow, spindle-shaped mite, measuring 185–205 microns long. The feather-claws are 4-rayed; the dorsal shield is produced anteriorly and marked with a design; and the coverflap of the female genitalia has 12 ribs in a single row. The males and protogynes are distinguished by having strong dorsal microtubercles and a pair of small anterior spines on the dorsal shield. The overwintering females (deutogynes) lack the anterior spines on the dorsal shield and microtubercles on the dorsum of the hysterosoma. The life history involves alternation of generations. The mites feed on both surfaces of the leaf blade. Deutogynes overwinter in the buds and bud scales.

Besides peach, *A. cornutus* attacks nectarine and almond. It is probably present throughout the range of its host plants.

References: Banks, *1905: 141;* Jeppson et al., *1975: 503;* Keifer, *1938b: 306;* Wilson and Cochran, *1952: 443.*

**Rosaceae**

***Rubus procerus* P. J. Muell. Himalaya Berry**

***Rubus vitifolius* Cham. & Schlectend. Blackberry**

**Redberry disease and delayed drupelet ripening caused by *Acalitus essigi* (Hassan) (pl. 56)**

The redberry mite, *Acalitus essigi,* was found on Himalaya berry in California in 1921. It was subsequently reported on blackberry in California and Washington. It causes the well-known redberry disease, which forms an interesting and attractive contrast as a result of the mite feeding on the fruit between the drupelets and around the core. Infested berries show swollen, brilliant red or pink and greenish drupelets among unaffected purple or maroon drupelets. Some berries have entirely red drupelets. Affected berries remain red or green and do not ripen normally. Often berries of late maturing varieties are seriously infested.

This is a yellowish or colorless, spindle-shaped mite, measuring about 140 microns long. The featherclaws are four-rayed; the tibia of leg I lacks setae; the dorsal shield has a somewhat lyre-shaped design with long and short median ridges; the hysterosoma is completely covered with pointed microtubercles; and the coverflap of the female genitalia has curved, broken, transverse ridges and granules. The mites migrate from the cane buds to developing flowers or from bud scales to green berries. Oviposition occurs in the buds in early March. The mite population reaches a peak in September and decreases in the fall and winter. The mites can be found in the buds or in between old bud scales throughout the year.

Redberry disease is known primarily in California, Washington, Oregon, and Texas. The redberry mite, *A. essigi,* may be confused with *Acalitus orthomera* (Keifer), a bud mite pest of boysenberry (*Rubus ursinus* var. *loganobaccus* (L. H. Bailey) L. H. Bailey), native blackberry (*Rubus* sp.), and dewberry (*Rubus macropetalus* Dougl. ex Hook.) in California. Infestation of dewberry by *A. orthomera* causes bud distortion and shoot stunting that often result in killing of the buds. Recently specimens of *A. orthomera* were found in the buds of blackberry (*Rubus* sp.) from Maryland that show symptoms of redberry disease.

References: Hanson, *1933: 3;* Hassan, *1928: 380;* Jeppson et al., *1975: 463, 465;* Keifer, *1941: 205.*

**Rutaceae**

***Citrus* spp. Grapefruit, Lemon, Lime, Orange**

**Russeting and bronzing of leaves, twigs, and fruit caused by *Phyllocoptruta oleivora* (Ashmead) (pl. 57)**

The citrus rust mite, *Phyllocoptruta oleivora,* has been known in Florida since 1879. It is now found in most of the citrus-growing areas of the world. Although this mite causes russeting of the rind of oranges and grapefruit, it appears to be more of a serious pest of lemons in California. Its feeding destroys the epidermal cells of the rind, producing silvering or russet effects. The rind of the affected fruit is thicker than normal, and the fruit tends to be smaller. Another result of the infestations on lemons and grapefruit is a condition known as "sharkskin," in which the outer layer of the skin can be peeled. Heavy populations of mites feeding on leaves and twigs can also cause bronzing.

*Phyllocoptruta oleivora* is a robust, spindle-shaped, yellow-to-brownish mite, measuring 150–165 microns. The featherclaws are five-rayed; the dorsal shield is produced anteriorly, with a well-defined longitudinal curved ridge at the middle; and the dorsal setae are directed inward. An outstanding feature of this mite is the presence of a broad trough on the dorsum of the opisthosoma. The microtubercles are present only ventrally, and the coverflap of the female genitalia has 14–16 ribs in a single row. The mites do not overwinter. They are found on the underside of the leaves, on stems, and in protected areas of the fruit. Development from egg to adult takes 7–10 days in the summer and 14 or more days in the winter. The biology and control of *P. oleivora* have been the subject of considerable study. Jeppson et al. (*1975*) give a useful summary.

*Phyllocoptruta oleivora* is one of the most injurious pests of oranges and grapefruit in Florida and Texas and of lemons in California. It has been eradicated in Arizona.

References: Ashmead, *1879: 160;* Jeppson et al., *1975: 485;* Keifer, *1938a: 193;* Yothers and Mason, *1930: 1–56.*

**Solanaceae**

***Lycopersicon lycopersicum* (L.) Karst. ex Farw. Tomato**

**Browning and withering of foliage and russeting of fruit caused by *Aculops lycopersici* (Massee) ( = *Phyllocoptes destructor* Keifer) (pl. 58)**

The tomato russet mite, *Aculops lycopersici,* is a serious pest of tomato plants. The first signs of infestations are noticed on the lower stem and leaves, which turn brown; later the leaves wither. Heavy mite attacks may affect the fruit, with the skin becoming russet and roughened. If the infestation is not prevented, the plants eventually wither and die; usually about one-half of the crop is lost.

*Aculops lycopersici* is a robust, spindle-shaped, whitish-to-yellowish mite; the female measures 150–180 microns long and the male 140–150 microns. The featherclaws are 4-rayed; the peculiar structure of the dorsal shield and its design are characteristic features of this mite; the microtubercles on the hysterosoma are pointed and confined ventrally; and the coverflap of the female genitalia has 8–10 short, longitudinal ribs. The mites are vagrants and feed on the surface tissues of the leaves, stems, and fruit. The life cycle is completed in about 7 days; reproduction occurs during early May through November.

*Aculops lycopersici* was described as *Phyllocoptes destructor* by Keifer in 1940 from tomato plants in California. It was originally from Australia, and it is a serious pest of this plant during the summer and early fall in New South Wales. Its distribution is probably worldwide. Other hosts are common nightshade (*Solanum nigrum* L.), datura (*Datura inoxia* Mill.), popolo (*S. sodomeum* L.), petunia (*Petunia* sp.), and potato (*S. tuberosum* L.), all of the family Solanaceae. *Aculops lycopersici* should not, however, be confused with *Eriophyes lycopersici* (Wolffenstein), which causes patches of white hairy erineum on the stems and underside of the leaves of tomato plants.

References: Bailey and Keifer, *1943: 706;* Jeppson et al., *1975: 452;* Keifer, *1940c: 160;* Massee, *1937: 403.*

**Theaceae**

***Camellia japonica* L. Common Camellia**

**Discoloration of leaves, floral parts, and bud scales caused by *Acaphylla steinwedeni* Keifer, *Calacarus carinatus* (Green) (= *"Epitrimerus" adornatus* Keifer), and *Cosetacus camelliae* (Keifer) (pl. 59)**

The following three eriophyid mites are serious pests of camellia:

*Acaphylla steinwedeni* is a leaf vagrant that occurs on camellia leaves with *Calacarus carinatus*. Infestation may cause bronzing of the leaves. The mite is spindle shaped and yellow or orange; the dorsal setae are very short; the featherclaws are curiously bifurcate and three-rayed; and the hysterosoma has microtubercles ventrally. The bifurcate featherclaws readily separate *A. steinwedeni* from *C. carinatus*. Both species overwinter on the leaves. The former has been found only on camellia in California, Alabama, and Florida.

*Calacarus carinatus* is another leaf vagrant that causes bronzing of the upper surface and downward folding of the leaf edges. It also deposits debris on the leaves as white streaks of cast skins. The mite is spindle shaped and striking in appearance because of its purple color and the waxy exudates that form ridges on the dorsal shield and hysterosoma. The dorsal setae are absent, the featherclaws are five-rayed, and the hysterosoma has microtubercles ventrally. *Calacarus carinatus* infests camellia and also cranberry bush (*Viburnum opulus* L., Caprifoliaceae), but no injury has been observed on the latter. It has been reported in California, Florida, and Georgia.

*Cosetacus camelliae* is found under flower bud scales. Colonization of the buds results in browning at the edge of bud scales and floral parts. The flower buds turn brown and drop before blooming, and, according to Gibson (*1967*), dropping of buds, distortion of opening flowers, and premature drop of flowers occur. The mite also causes leaves to appear rusty. *Cosetacus camelliae* is white and wormlike; the dorsal setae are long and directed backward; the featherclaws are six-rayed; and the hysterosoma is completely covered with microtubercles. This mite occurs in California, Florida, and probably much of the Southeastern United States on camellia.

**Ericaceae**

***Gaylussacia baccata* (Wangenh.) C. Koch. Huckleberry**

***Vaccinium* spp. Blueberry**

**Bud blister, rosette, and fruit deformation caused by *Acalitus vaccinii* (Keifer) (pl. 60)**

*Acalitus vaccinii* is one of the major pests of blueberry. This mite attacks the buds, which become succulent, fleshy, and closely packed in clusters or rosettes on the stem; they fail to expand and bloom. This results in the production of fewer berries and leaves, or bud loss. Affected berries appear roughened and malformed and may show small, reddish pimples or blisters. Infested plants in the field are easily recognized by the clustering or rosetting of the buds, which are sometimes abundant, and by marked discoloration of berries.

The mite is robust, yellowish white, and spindle shaped, measuring 185–210 microns long. The featherclaws are 6-rayed; the tibia of leg I lacks setae; the dorsal shield has 2 indistinct submedian curved ridges; the hysterosoma is covered with elliptical microtubercles; and the coverflap of the female genitalia has 8–10 ribs in a single row. The mites spend the entire life cycle of about 15 days in the bud. An increase in mite population occurs throughout the fall and winter, reaching its peak in December and January, when the injury becomes severe.

*Acalitus vaccinii* was first collected during March–April in North Carolina. It is present throughout the Eastern States and along the coastal areas from Canada to Florida and Texas. Keifer (*1941*) stated that this mite "occurs on wild and cultivated vacciniaceous plants, especially high bush types of *Vaccinium* spp." *Acalitus vaccinii* also infests huckleberry.

References: Cromroy and Kuitert, *1973: 1;* Jeppson et al., *1975: 469;* Keifer, *1939c: 329; 1941: 196;* Neunzig and Sorensen, *1976: 5.*

**Malvaceae**

***Gossypium* spp. Cultivated and Wild Cotton**

**Leaf blister, bud injury, and foliage deformation caused by *Acalitus gossypii* (Banks) (pl. 61)**

*Acalitus gossypii* has been recognized for many years as a destructive pest of cultivated cotton. The mites attack the flower buds, and any parts arising from the buds may be infested. The leaves are contorted and crumpled or aborted and with short petioles. The flowers are covered with fine white hairs and the petals fail to open. Young plants show stunted, irregular growth and lack flowering branches. Mite feeding on the undersurface of the leaves causes chlorosis and whitish blisters. Damage appears severe on plants that were attacked when young.

This mite is wormlike and colorless, measuring over 200 microns long. The featherclaws are four-rayed; the tibia of leg I lacks setae; the dorsal shield has five longitudinal lines; the microtubercles are rounded; and the coverflap of the female genitalia lacks ribs. The mites are leaf vagrants. The life cycle is apparently short, and the mites reproduce throughout the year.

*Acalitus gossypii* infests various wild and cultivated cotton. It has been reported from southern Florida, Puerto Rico, the West Indies, Venezuela, and Brazil. This mite is similar to *Acalitus sphaeralceae* Keifer, which infests the leaves of globemallow (*Sphaeralcea* sp.) in Arizona. So far the latter mite has not been found on cotton.

References: Banks, *1904: 56;* Fife, *1937: 169;* Jeppson et al., *1975: 465;* Keifer, *1965c: 3.*

**Rosaceae**

***Pyrus communis* L. Common Pear, Pear**

**Leaf blister caused by *Phytoptus pyri* Pagenstecher (pl. 62)**

The pearleaf blister mite, *Phytoptus pyri,* has been an important pest of pear for many years. Feeding of the overwintering mites causes leaf blisters on the developing leaves as the buds commence growth in the spring. At first blisters appear as reddish or pinkish swellings, later as rough red swellings on the lower surface of the leaf blade. Often they coalesce, covering a large area of the leaf blade alongside the midrib. As blisters become infested with mites, they turn dark brown to black, and by the end of the growing season the affected tissue has become dead and shrunken. Blisters that are not colonized by mites are pale green. Later they may become inhabited by mites from old nearby blisters. However, blisters without exit holes never contain mites.

This mite is yellowish, slender, and wormlike, measuring 200–230 microns long. The featherclaws are 4-rayed; the dorsal shield has a distinct design of a broken median ridge flanked by a pair of longitudinal ridges, with the ends curving and joining posteriorly; the dorsal setae are directed forward; the microtubercles are elliptical; and the coverflap of the female genitalia has 10 ribs in a single row. The habits and life cycle of *P. pyri* have been observed by several workers, including Burts (*1959*) in the Pacific Northwest. The mites in the blisters develop several generations during late spring and summer. Development from egg to adult takes 20–30 days during the spring and 10–12 days in the warmer part of the summer. A useful summary is given in Jeppson et al. (*1975*).

*Phytoptus pyri* belongs to a group of eriophyids found on rosaceous plants, but it is confined to pear. Another eriophyid mite, *Phytoptus pseudoinsidiosus* (Wilson), also a pest of pear trees in certain areas of the Western United States, causes the same type of leaf blisters. It should not be confused with *P. pyri.*

References: Burts, *1959: 42;* Jeppson et al., *1975: 422;* Keifer, *1938a: 183;* Pagenstecher, *1857: 48;* Wilson, *1965: 327.*

**Rosaceae**

***Sorbus californica* Greene Mountain Ash**

***Sorbus scopulina* Greene Mountain Ash**

**Leaf blister caused by *Phytoptus sorbi* Canestrini and erineum caused by *Phyllocoptes calisorbi* Keifer (pl. 63)**

Two species of eriophyids producing different leaf symptoms are found on mountain ash. Because the taxonomy of the mites is complex, we are simplifying the descriptive entry of the two forms here.

(1) Blisters on leaves are similar to those on other rosaceous plants, particularly pear. They are small, puckered swellings on the upper surface of the leaves, varying from yellowish when the blisters first appear to brown on maturing. *Sorbus scopulina* in California is usually heavily infested by *Phytoptus sorbi.* This mite closely resembles *Phytoptus pyri* Pagenstecher, the pearleaf blister mite, and belongs to a complex of species with four-rayed featherclaws found on rosaceous plants.

(2) Large patches of whitish erineum may be found on the lower surface of the leaves of *Sorbus californica.* The erineum hairs are elongate, of varying length and form, at first whitish, and later turning brown (see pl. 7, *B,* for detailed structure). They are abundant on plants in the shade.

*Phyllocoptes calisorbi* is distinct and easily separable from *Phytoptus sorbi,* but here again this erineum-forming mite belongs to a complex of species (*Phyllocoptes goniothorax* complex) that attacks pomaceous Rosaceae. For precise identification of the species, send the specimens to a specialist.

## Leaf Deformation, Distortion, Vein Atrophy, and Fruit, Bud, and Flower Abnormalities

**Berberidaceae**

***Mahonia dictyota* (Jeps.) Fedde Holly Grape, Oregon Grape**

**Leaf fold and twisting caused by *Eriophyes caliberberis* (Keifer) (pl. 64)**

The inclusion of this injury is to illustrate an uncommon type of foliage distortion caused by an eriophyid. Colonization of a leaf by *Eriophyes caliberberis* results in considerable contortion; the leaf margin is curled upward, folded, and twisted across the upper surface toward the midrib. The leaf fold may involve the entire length of the leaf margin, with one or two windings forming a tube. The folded leaf eventually becomes crumpled and brown. The mite colonies are found in the tight leaf folds.

This mite is yellowish white and somewhat spindle shaped, measuring 175–195 microns long. The featherclaws are 5-rayed; the dorsal shield is unmarked except for 2 strong, short ridges posteriorly between the setal bases; the microtubercles are elliptical; the coxae have a few granules; and the coverflap of the female genitalia has 12 ribs in a single row.

*Eriophyes caliberberis* inhabits the leaf folds and buds. The mites were collected in November on *Mahonia dictyota,* an evergreen shrub found in the dry, rocky areas at 500–1,800 meters in California.

**Caprifoliaceae**

***Symphoricarpos rivularis* Suksd. Snowberry**

**Leaf roll caused by *Phyllocoptes triacis* Keifer (pl. 65)**

The infested leaf is usually folded at the distal end of the blade, with the margin rolled tightly over the upper surface; at times only the lateral margin of the leaf is infolded, forming a podlike fold. The rolls are glabrous, somewhat thickened, and conspicuous against the green leaf blade. Although many leaves show severe deformation, the plant does not seem to be affected by the damage.

*Phyllocoptes triacis* is a robust, spindle-shaped, yellowish-white eriophyid, measuring 190–215 microns long. The featherclaws are eight-rayed. A distinguishing character is the presence of three spines on the anterior margin of the dorsal shield and a dorsal ribbon design formed by two median ridges. The dorsal setae are directed forward; the microtubercles are spinelike; and the coverflap of the female genitalia has 12 strong ribs.

In Oregon this mite occurs together with *Eriophyes brownei* Keifer in the hollow of the leaf fold; it was collected in May. In California, however, *P. triacis* is the only species present. The host is snowberry, which is found from Alaska to Montana and California.

**Gramineae**

***Cynodon dactylon* (L.) Pers. Bermuda Grass**

**Terminal shoot and leaf blade distortion caused by *Eriophyes cynodonis* (Wilson) (pl. 66)**

The mites are abundant in the folded terminal shoots, where their feeding apparently inhibits the expansion of the leaves. This results in the twisting of the folded terminal shoot and subsequent infolding, bending, and twisting of the leaf blade. Infested Bermuda grass may easily be recognized by the contorted terminal leaf blades.

*Eriophyes cynodonis* is a robust, spindle-shaped, whitish or yellowish mite, measuring 170–211 microns long. The featherclaws are 8-rayed; the dorsal shield is produced anteriorly and marked with 2 longitudinal ridges at the anterior angle of the shield running laterally; the microtubercles are minutely pointed; the accessory setae are present; and the coverflap of the female genitalia has 10 longitudinal ribs.

Specimens were collected on infested Bermuda grass in California and Arkansas. This mite is not to be confused with *Eriophyes cynodoniensis* (Sayed), which also infests Bermuda grass but causes a rosettetype injury.

Reference: Wilson, *1959: 142.*

**Nyssaceae**

***Nyssa sylvatica* Marsh. Pepperidge, Sour-Gum, Tupelo**

**Leaf edge roll caused by *Eriophyes dinus* Styer & Keifer and leaf gall caused by *Cenalox conyssae* Styer & Keifer, *C. nyssae* Keifer, and *E. nyssae* Trotter (pl. 67)**

Two species of *Eriophyes* infest tupelo. Their feeding causes leaf edge roll and leaf galls. *Eriophyes dinus* is responsible for the irregularities of the leaf margin, which consist of thickened rolled edges with one to two windings, and the transforming of the leaf tip into a twisted or spiral tube. At first the colonized areas are the same color as the rest of the leaf, later becoming reddish, and finally brown. The thickness of the leaf roll is variable, and the whole length of the leaf margin may become infested, producing an attractive crinkly, wavy leaf. Rolled edge leaf sometimes has beadlike galls colonized by *Eriophyes nyssae.* These galls, which also occur on the upper surface of the leaf, are small and may be solitary or coalesced.

*Eriophyes dinus* and *E. nyssae* are not separable by morphological characters. Both have three-rayed featherclaws; the dorsal shield is not marked with a design; the hysterosoma of primary females and males has microtubercles, whereas they are lacking or weakly developed in the overwintering females; and the coverflap of the female genitalia lacks ribs.

Besides the *Eriophyes* mites, two distinctive species, *Cenalox nyssae* and *C. conyssae,* also infest tupelo. Specimens were found recently on the underside of the leaves in galls along the midribs and veins. The simple distinctions of the two galls concern their form, position, and texture. Those caused by *C. nyssae* are small, rounded pockets filled with erineum; the galls appear alongside the midrib at angles of lateral veins. The *C. conyssae* galls are rough, open pockets filled with fleshy lobes, and they appear alongside the veins. Both galls form slight swellings on the upper surface of the leaves.

*Cenalox* mites are spindle shaped and whitish, with three- or four-rayed featherclaws and an obscure design on the dorsal shield. The basic morphological differences and similarities between these two gall-forming species are discussed by Styer and Keifer (*1978*).

The host is *Nyssa sylvatica,* commonly known locally as tupelo. The mites were collected in New York, Maryland, and from North Carolina to Georgia and Ohio.

References: Keifer, *1961: 7;* Styer and Keifer, *1978: 7;* Trotter, *1903: 67.*

**Punicaceae**

***Punica granatum* L. Pomegranate**

**Leaf roll caused by *Eriophyes granati* (Canestrini & Massalongo) (pl. 68)**

This is an interesting tubular leaf roll, which consists of a downward tight rolling and curling of the whole length of the leaf margin into a tube. Eventually the infested margin rolls toward the midrib but does not cover it. The mites are wrapped in the thickened turned-over leaf edge, where they live and reproduce inside the roll. In some plants, infestations are so heavy that nearly every young leaf is rolled, distorted, and twisted.

*Eriophyes granati* is a yellowish, somewhat robust eriophyid, measuring 165–180 microns long. The featherclaws are 4-rayed; the distinctive dorsal shield design has curved, straight ridges, with the median weakened anteriorly but ending dart shaped posteriorly; the microtubercles are rounded or elliptical; the coxae are covered with fine granules; and the coverflap of the female genitalia has 14–16 ribs in a single row.

This species was originally found in Italy on pomegranate, a widely cultivated plant in tropical and subtropical areas. Specimens were found in California on the same host.

References: Canestrini and Massalongo, *1894: 465;* Jeppson et al., *1975: 452;* Keifer, *1952d: 9, 13, 29.*

**Rutaceae**

***Citrus* spp. Grapefruit, Lemon, Lime, Orange, Other Citrus**

**Deformed buds, flowers, leaves, and fruit caused by *Eriophyes sheldoni* Ewing (pl. 70)**

The citrus bud mite, *Eriophyes sheldoni,* has been known as a serious pest of lemon and orange trees for many years. Its feeding within the buds invariably results in distortion of shoot growth, excessive and grotesque deformation of fruit, foliage, and blossoms, discoloration of fruit, and more commonly the production of numerous buds. The last may develop abortive twigs in tight clusters resembling witches'-broom and bunched terminal growth of distorted stems and leaves. Most malformed fruit drops prematurely. Mature lemon fruit shows blackened areas on the rind beneath the sepals (buttons), where large colonies of mites are concealed. Deformed leaves and blossoms assume various shapes; the leaf blades are constricted at their middle, curled and twisted, and divided and divergent at the tips; and the blossoms are stunted and abnormal. The symptoms of injury on oranges are similar to those on lemons except fruit deformation is not so grotesque. Affected oranges usually develop to maturity, but they are commonly flattened, resembling the shape of tomatoes; or there are skin folds, seams and ridges, or small apertures in the stylar end.

*Eriophyes sheldoni* is a robust, wormlike mite, measuring 170–180 microns long; it varies from yellowish to pinkish, to orange. The featherclaws are 5-rayed; the dorsal shield has a variable design of indistinct short and broken or 2 parallel ridges running the entire length of the shield, and a median broken ridge that ends posteriorly as dart shaped; the microtubercles are elliptical; the coxae have fine granules; and the coverflap of the female genitalia has 10–12 ribs. The mites inhabit protected areas in the buds, in developing blossoms, and beneath the sepals (buttons) of the fruit. The life cycle has been summarized by Jeppson et al. (*1975*). It takes about 15 days during the summer and 20–30 days during the winter to develop from egg to adult.

*Eriophyes sheldoni* attacks lemons, oranges, limes, grapefruit, and other citrus. It probably occurs throughout the citrus-growing areas of the world. In California and New South Wales, *E. sheldoni* is important in coastal districts. Heavy infestations of lemons and oranges can cause great economic loss to citrus growers.

**Anacardiaceae**

***Mangifera indica* L. Mango**

**Leaf coating caused by *Cisaberoptus kenyae* Keifer (pl. 71)**

The whitish coating on mango leaves caused by *Cisaberoptus kenyae* generally resembles that produced by *Aculops knorri* Keifer on leaves of a sapindaceous tree. The coating develops at the petiole, just below the leaf blade on young leaves, and extends to the upper surface of the blade. It covers mainly the areas along the midrib and lateral veins and in between the veins. Narrow patches may be seen bordering the leaf margins. The material and structure are not known, although they are weblike and somewhat thickened.

*Cisaberoptus kenyae* is an interesting heteromorphic eriophyid mite. The body is flattened dorsoventrally and yellowish white, measuring 190–210 microns long. The featherclaws are elongate, bulbous, and with 17 or more fine rays; the gnathosoma is curiously spatulate, but normal males and females have the short, typical eriophyid gnathosoma; the dorsal shield is broad and unmarked, with a pair of posterior lobes near the base of the dorsal setae; the hysterosoma is covered with granular microtubercles; and the coverflap of the female genitalia has an irregular series of 14–16 ribs. Heteromorphic females are usually found at the border area of the webbing. Larger colonies of mites are under the weblike patches.

This species is known in East Africa, Southeast Asia, and Brazil on mango.

References: Keifer, *1966b: 1;* Knorr et al., *1976: 229.*

**Sapindaceae**

***Erioglossum rubiginosum* (Roxb.) Blume**

**Leaf webbing caused by *Aculops knorri* Keifer (pl. 72)**

This interesting phenomenon of web spinning and coating of the leaf surface by *Aculops knorri* is the first record among eriophyid mites. A second is mentioned under *Cisaberoptus kenyae* Keifer (p.156). The weblike patches on sapindaceous leaflets are initially dull grayish white, resembling powdery mildew, and later becoming shiny. Webbing may cover the entire upper surface of the leaflet; pinhead-sized webs are scattered at random over the surface, and small patches commonly border or lie along the grooves of the lateral veins. Affected areas of the leaflet under old patches show slight russeting or necrosis. Under the scanning electron microscope, the weblike coating consists of fine crisscrossing filaments and woven strands that form the fabric of the webbing.

*Aculops knorri* is a robust, brownish-orange, spindle-shaped mite, measuring 128–148 microns long. The featherclaws are 6-rayed; the dorsal shield is smooth, unmarked; the microtubercles are slender, elongate; and the coverflap of the female genitalia has 12 ribs. Numerous mites in all stages of development are found on the upper surface of the leaflet under the webbing. Infestation and web formation occur from April to June; approximately 5 percent of the leaves are affected. New leaves that emerge after the start of the rainy season are free from webbing.

This mite is known only from Thailand on *Erioglossum rubiginosum,* a common sapindaceous fruit tree native to tropical Asia and northern Australia.

References: Keifer, *1976: 2;* Knorr et al., *1976: 228.*

**Gramineae**

***Triticum aestivum* L. Wheat**

***Zea mays* L. Corn**

**Mosaic virus disease of corn and wheat and red streak of corn caused by *Eriophyes tulipae* Keifer (pl. 73)**

*Eriophyes tulipae* is the vector of wheat streak mosaic virus (WSMV) and wheat spot mosaic virus (WSpMV). These viruses are destructive to wheat, causing chlorotic spots, necrosis, and stunting; sometimes they kill the plant. According to Jeppson et al. (*1975*), WSMV may be transmitted by *E. tulipae* to barley (*Hordeum vulgare* L.), oats (*Avena sativa* L.), rye (*Secale cereale* L.), and certain wild annual grasses. Barley and rye have been known to be an occasional source from which *E. tulipae* may transfer WSMV to spring wheat-fields. The mites may colonize other grasses, such as wheatgrass (*Agropyron* sp.), Canada wild rye (*Elymus canadensis* L.), Virginia wild rye (*Elymus virginicus* L.), Indian ricegrass (*Oryzopsis hymenoides* (Roem. & Schult.) Ricker.), and Canada bluegrass (*Poa compressa* L.), all of which may become infected with the virus. *Eriophyes tulipae* can also infest some common perennial grasses, including Wheeler bluegrass (*Poa* sp.), western wheatgrass (*Agropyron* sp.), and foxtail barley (*Hordeum* sp.), which are immune to WSMV. It also transmits both WSMV and WSpMV to corn. All stages of the mites, except the egg, carry the virus.

In addition, the feeding of the mites on corn kernels causes a disease known as kernel red streak, whereby discolored corn ears show red-striped pericarps. The color ranges from deep red in yellow kernels to pink or purple in white kernels. Streaked kernels may appear randomly but more concentrated at the ear tips. Mite feeding injury on young corn is indicated by spotting, curling, or rolling of the leaves. On wheat, high mite populations result in tightly curled, rolled, or trapped leaves. Numerous reports have been published on this mite and its relation to viruses and feeding injury to both corn and wheat. See Slykhuis (*1955, 1962, 1967*), Slykhuis et al. (*1968*), and Oldfield (*1970*). A useful summary is given by Jeppson et al. (*1975*).

This mite is whitish, slender, and somewhat spindle shaped, measuring 210–250 microns long. The female has 7-rayed featherclaws; those of the male are 6-rayed and usually shorter than those of the female; the dorsal shield has 1 short median ridge posteriorly, flanked by 2 divergent ridges running the entire length of the shield; the microtubercles are elliptical; the coxae are covered with minute granules; and the coverflap of the female genitalia has 10 long ribs.

Nault and Styer (*1969*) observed the biology in Ohio as follows: The mites are found in all stages of development on wheat, in curled leaf margins, in unopened leaves, in leaf sheaths and ligules, and in glumes on the heads. On corn, they are found in rolled leaves, on kernels and silks, and under husks of the ear. They overwinter on wheat; high populations were found in the spring and early summer and on corn in late summer and early fall. As the wheat heads dry up in July, the mites disperse to corn; in the fall when the corn has matured, they move to the fall-planted winter wheat, completing the cycle. Corn apparently has a significant role in the biology and transmission of mosaic virus.

For further discussion on mite biology and habits, see Jeppson et al. (*1975*).

*Eriophyes tulipae* is common and widespread throughout much of the area where corn and wheat are grown in the United States and Canada. Besides the cultivated crops and wild grasses (Gramineae) mentioned here, other hosts include garlic and onions (*Allium* spp., Amaryllidaceae) and tulip (*Tulipa* sp., Liliaceae), where this mite is found between layers in the bulbs.

**Moraceae**

***Ficus carica* L. Fig**

**Mosaic virus disease caused by *Eriophyes ficus* Cotte (pl. 74)**

No proof was provided until 1955 that *Eriophyes ficus* was the vector of a virus causing fig mosaic. This mite proved to be an efficient vector. In addition to transmitting this virus, it causes leaf distortion, chlorosis, russeting, and scarring of the eye scales and seeds of the fruit. It occasionally causes stunting of twigs and premature leaf drop.

*Eriophyes ficus* is a yellowish, slender, spindle-shaped mite; the female measures 160–202 microns long and the male about 140 microns. The featherclaws are five-rayed; the dorsal shield is marked with longitudinal ridges, the lateral ones forming closed cells anterior to the setal bases; the hysterosoma is covered with elliptical microtubercles; and the coverflap of the female genitalia has eight ribs. All stages and both sexes of the mites are found on the leaves, in the buds and fruit, and occasionally on the stems throughout the year. Eggs are laid in the buds, on branches, and on both surfaces of the leaves following bud burst in the spring. During July many mites move off the leaves to enter the fruit, where they lay eggs among the eye scales, and all stages are found inside the fruit. The mites overwinter in the buds.

Fig mosaic virus has been reported from fig. The vector, *E. ficus,* is widespread on this plant in California; it also occurs in Oregon, Italy, and India. It is likely that both virus and mite will be found in most areas where figs are grown.

**Rosaceae**

***Rosa* spp. Cultivated and Wild Roses**

**Rose rosette virus disease caused by *Phyllocoptes fructiphilus* Keifer (pl. 75)**

Allington et al. (*1968*) demonstrated in Nebraska that rose rosette virus could be transmitted to cultivated roses by *Phyllocoptes fructiphilus*. Infected wild rose plants generally exhibit malformation of the stems and leaves and multiplication of stunted shoots, with the individual structures forming a bunch. The appearance is that of a rosette. A common rosette virus symptom on cultivated roses is the premature breaking of the axillary buds, which become malformed, and stunted shoots; the leaves may appear normal, but those toward the tips are small and deformed. On other varieties, the affected leaves are puckered; they may turn red or become chlorotic. The floral parts are aborted and distorted. A few rose plants may show an increase in thorns.

The mite is a robust, yellowish-to-yellowish brown, spindle-shaped eriophyid, measuring 140–170 microns long. The featherclaws are five-rayed; the dorsal shield is marked with a design; the dorsal setae are directed forward and dorsocentrally; the microtubercles are elliptical; and the coverflap of the female genitalia has six to seven ribs. Specimens were originally found in wild rose hips (*Rosa californica* Cham. & Schlechtend.) in California. In cultivated roses, the mites may be seen in the angles between the leaf petioles and axillary buds; they are in the bud scales during the winter and early spring. The mite population becomes numerous in mid-June and early July, reaching its peak in September. A closely related mite, *Phyllocoptes slinkardensis* Keifer, also occurs on infected rose plants.

Rose rosette disease is found in several species of wild and cultivated roses in California, Nebraska, Wyoming, and Manitoba, Canada. Wild roses apparently serve as a reservoir for the virus.

## Glossary

ACARI, ACARINA—Small to minute arachnids, including mites and ticks, with body divided into gnathosoma (mouthparts) and idiosoma and with two to four pairs of legs in adult stage.

ALTERNATION OF GENERATIONS—Type of reproduction as seen in some eriophyid mites, when two forms are involved during the life cycle, one consisting of only females (deutogynes) and the other of individuals of both sexes (protogynes and males).

APICAL—At the tip, the distal end.

BASAL—At the base.

BLISTER—Injury to leaves or fruit by mite invasion of plant epidermal tissue, resulting in leaf withering and fruit swelling.

BRACT—Reduced or scalelike leaf in a flower cluster.

BROOMING—Cluster of stunted, slender twigs in crowded bunches arising basally or apically from an axis with greatly shortened internode.

CAPITATE—Type of hair with knobbed tip in erineum or gall.

CATKIN—Spikelike inflorescence bearing scaly bracts and apetalous unisexual flowers, characteristic of oak, walnut, and willow.

COVERFLAP—Shaped like a scoop; covers genital structure of an eriophyid mite.

COXA (pl. COXAE)—Basal segment of the leg, by which it is articulated to the body.

DEUTOGYNE—Strictly in Eriophyoidea, an overwintering female adult morphologically different from the protogyne.

ERINEUM—Form of gall; abnormal growth of hairs from leaf epidermis caused by mite attacks, especially Eriophyidae.

ERIOPHYIDAE, ERIOPHYOIDEA—Specifically wormlike mites with two pairs of legs.

FAMILY—Taxonomic category, including one or more genera or tribes, ending in idae (ex. Eriophyidae).

FEATHERCLAW—Single branched or rayed structure at end of an eriophyid leg.

GALL—Strictly defined, whatever its form, an abnormal growth on a plant as a result of a parasite attack; as used here, it is caused by eriophyid mites.

GENITALIA—All genital or reproductive structures, especially external sex organs.

GNATHOSOMA—Mouth and mouthparts; in Eriophyoidea, commonly referred to as rostrum by H. H. Keifer; anterior part of acarine body.

HETEROMORPHIC—Having different forms at different life stages.

HYSTEROSOMA—In eriophyids, elongate posterior part of body from anterior two pairs of legs; thanosome according to H. H. Keifer.

IDIOSOMA—Includes body of mites posterior to the gnathosoma.

INDUSIUM—Small flap of epidermal tissue that covers a sorus; in bracken, a thin flap of pale tissue continuous with the underside edge of the pinnule.

INFLORESCENCE—Flowering part of a plant or flower cluster.

INQUILINE—Mite or insect guest of other mites or insects, or organism that lives as a guest in the gall or erineum of other mites.

LIFE CYCLE—Series of changes or period of time from egg to adult stage.

LIGULE—Thin membrane attached to a leaf of grass at the point where the blade meets the leafstalk; projection from top of the sheath in grasses, palms, and some other plants.

MICROTUBERCLE—In Eriophyoidea, a minute and rounded or pointed hysterosomal structure.

MITE—Any numerous minute arachnids (Acarina, Acari) often found in almost every habitat, infesting plants, animals, and stored food.

MORPHOGENESIS—Structural changes during development; evolution of morphological characters.

OPISTHOSOMA—Section of body posterior to the legs; abdomen according to H. H. Keifer.

PAPILLA (pl. PAPILLAE)—Minute soft projection.

PEDICEL—Stem or stalk of a flower.

PERICARP—Wall of a ripened ovary or fruit.

PETIOLE—Stalk of a leaf.

PINNA—Primary leaflet or a featherlike leaf.

PINNULE—Any leaflet of a pinnate leaf; segment of a pinna leaflet.

PROTOGYNE—One of two adult female forms of the same species and similar to the male.

ROSE HIP—Fruit of a rose, consisting of fleshy floral cup and true fruits (achenes) enclosed within it.

ROSETTE—Cluster of flowers, leaves, or stunted twigs in crowded circles arising basally or apically from an axis with shortened internode.

RUSSETING—Brownish roughened area on leaves or skin of fruit.

SAPINDACEOUS—Applied to a tropical plant of the soapberry family Sapindaceae.

SETA (pl. SETAE)—Hair.

SHEATH—Basal part of a grass leaf or of a palm leaf when surrounding the stem.

SHIELD—Anterior dorsal part of the eriophyid body, which is broad, smooth, or marked with a design.

SORUS—Cluster of sporangia or spore case in ferns.

SUPERFAMILY—Category in classification above family and below order, ending in oidea (ex. Eriophyoidea).

SYNONYM—One of two or more names given to the same species or genus previously named and described; a name rejected as being incorrectly applied.

TUBERCLE—Small, lobelike body structure bearing a seta.

UMBEL—Flat-topped or convex inflorescence in which the flower pedicels arise from the same point.

VACCINIACEOUS—Applied to plants of the genus *Vaccinium* L. (blueberry, huckleberry, cranberry).
