ENZYMES OF ECDYSTEROID 3-EPIMERIZATION IN MIDGUT CYTOSOL OF MANDUCA SEXTA: pH OPTIMA COSUBSTRATE KINETICS, AND SODIUM CHLORIDE EFFECT*

GUNTER F. WEIRICH, MALCOLM J. THOMPSON and JAMES A. SVOBODA

Insect Hormone Laboratory, Agricultural Research Service, U.S. Department of Agriculture, Beltsville, MD 20705, U.S.A.

Abstract—Five enzyme activities in midgut cytosol of Manduca sexta last instar larvae are potentially involved in the interconversion of 3β-hydroxyecdysteroids, 3-oxoecdysteroids, and 3α-hydroxyecdysteroids. A Sephadex G-25-filtered high-speed supernatant was used to determine some of the characteristics of the corresponding enzymes. The pH optima of ecdysone oxidase and NADH-dependent 3-oxoecdysteroid 3α-reductase were 7.5, the pH of the midgut cytosol was 7.9. The apparent kinetic parameters for the NADH-dependent 3α-reductase were $K_m$ (for NADH) = 80.8 ± 10.8 μM and $V_{max}$ = 0.58 ± 0.30 nmol/min/mg protein, and for the NADPH-dependent 3α-hydroxyecdysteroid 3β-reductase, $K_m$ (for NADPH) = 19.3 ± 2.5 μM and $V_{max}$ = 4.39 ± 0.40 nmol/min/mg protein. NAD$^+$ and NADP$^+$ inhibited the enzymatic 3-oxoecdysteroid reductions, but the reactions were not reversible (i.e. no conversion of ecdysone or 3-epiecdysone to 3-dehydroecdysone). Sodium chloride (0.2 M) inhibited the 3α-reductase activity with NADH and strongly increased the 3α-reductase activity with NADPH.

Key Word Index: Ecdysone oxidase; 3-oxoecdysteroid 3-reductase; 3-epiecdysone; 3-dehydroecdysone; 3α-hydroxyecdysteroid; 3β-hydroxyecdysteroid; Manduca sexta; midgut; cytosol; NADH; NADPH; sodium chloride

INTRODUCTION

3α-Hydroxyecdysteroids (e.g. 3-epiecdysone, 3-epi-20-hydroxyecdysone) are found in many insect species and are presumed to be inactivation products of the biologically much more active 3β-hydroxyecdysteroids (Rees, 1989; Lafont and Connat, 1989; Thompson et al., 1990). The first reported in vitro conversion of ecdysone (E) to 3-epiecdysone (E') (= 3-epimerization) was accomplished with a soluble enzyme preparation from Manduca sexta L. midgut and was thought to be a two-step reaction, consisting of an oxygen-dependent oxidation of E to 3-dehydroecdysone (3D), and a stereospecific reduction of 3D to E' that required NADH or NADPH as cosubstrate (Nigg et al., 1974; Mayer et al., 1979) (Fig. 1). In recent years this reaction mechanism has been verified in studies with enzyme preparations from (mid)guts of Pieris brassicae (Blais and Lafont, 1984), Spodoptera littoralis (Milner and Rees, 1985), and Manduca sexta (Weirich, 1989; Weirich et al., 1990a). These studies have also demonstrated the existence of another reductase, catalyzing the reconversion of the 3-oxo intermediate to the 3β-hydroxyecdysteroid (3-oxoecdysteroid 3β-reductase).

We recently reported the potential interrelationships of the M. sexta ecdysone oxidase and 3-oxoecdysteroid 3-reductases and the apparent kinetic parameters obtained by varying the concentrations of the ecdysteroid substrates (Weirich et al., 1990a). In the present communication we report the pH optima, the apparent kinetic parameters obtained by varying the concentrations of the nicotinamide adenine dinucleotide cosubstrates, and the effects of oxidized dinucleotides (NAD$^+$, NADP$^+$) and of sodium chloride on the M. sexta enzymes.

MATERIALS AND METHODS

Chemicals

Ecdysone was obtained from Simes Pharmaceuticals (Milan, Italy); E' and 3D were synthesized according to published procedures (Spindler et al., 1977). NAD$^+$, grade V-C; NADH, grade III; NADP$^+$, Sigma grade; NADPH, type X; and Leuconostoc mesenteroides Glc-6-P dehydrogenase were obtained from Sigma Chemical Co. (St Louis, Mo.) and Sephadex G-25 (fine), from Pharmacia LKB Biotechnology (Piscataway, N.J.).
Enzyme preparation

Tobacco hornworms (*M. sexta*) were reared to the late fifth instar on artificial diet (Hoffmann *et al.*, 1966). Midguts of "wandering" larvae were dissected and homogenized in the 80,000 g (3.6 × 10^6 rad s^-1) supernatant was prepared as described previously (Weirich and Adams, 1984; Thompson *et al.*, 1985). For the determination of the cytosol pH the Tris-sucrose-EDTA isolation buffer was substituted by 0.15 M potassium chloride solution.

The supernatant was fractionated on Sephadex G-25 (Weirich *et al.*, 1986), equilibrated with 12.5 mM Tris-HCl buffer, pH 7.5, containing 1.0 mM EDTA (buffer B). After a 5–10 min equilibration period, the reactions were started by addition of E, dissolved in 5 µl of methanol. The incubations were stopped by the addition of 4.0 ml methanol. The combined protein fractions (G-25 sup) were used for the incubations.

Protein concentrations were determined according to Lowry *et al.* (1951) with bovine serum albumin as standard.

Incubations

**Ecdysone oxidase.** Ecdysone (25–50 µM) and G-25 sup (2.1 mg protein) were incubated for 120 min at 30°C (Dubnoff metabolic incubator, 90–100 oscillations/min), in 1.0 ml of 30 mM potassium phosphate-10 mM Tris-HCl buffer, pH 7.5, containing 1.0 mM EDTA (buffer B). After a 5–10 min equilibration period, the reactions were started by addition of E, dissolved in 5 µl of methanol. The incubations were stopped by the addition of 4.0 ml methanol.

**3-Oxoecdysteroid 3β-reductase.** Incubation mixtures contained 3D (12.5–40 µM) and G-25 sup in 0.5–2.0 ml of buffer B or buffer C (same composition as buffer B, but pH 6.5). The concentrations of G-25 sup proteins in the incubation mixtures were 0.19–1.70 mg/ml for incubations containing NADH as cosubstrate, 0.07–0.13 mg/ml for incubations containing NADPH as cosubstrate. Except for the kinetic experiments, NADH or NADPH were added to the incubation mixtures to a final concentration of 0.6 mM.

The reaction mixtures were equilibrated in a Dubnoff metabolic incubator for 5–10 min (30 min for anaerobic incubations) at 30°C and 90–100 oscillations/min. The reactions were started by addition of 3D, dissolved in 50–100 µl of buffer A (for anaerobic incubations, injected through the venting tube). Incubation times were 10–20 min, and the incubations were stopped by addition of 4.0 ml methanol.

**Anaerobic incubations.** Ecdysone oxidase in the G-25 sup can reoxidize ecdysone formed by 3β-reductase in the incubation mixtures. As a result, the activity of the 3β-reductase will be slightly underestimated. Therefore, the reactions were linear for the duration of the incubations (monitored by u.v. absorption at 340 nm). The reaction rates were proportional to the amount of protein added.

For the determination of the pH optima the incubation mixtures were buffered with sodium citrate/phosphate (for pH 5–7), sodium phosphate (for pH 7–8), or glycine/NaOH/sodium phosphate (for pH 8–10). All buffers were made to an ionic strength of 0.20 and contained 1.0 mM EDTA. No conversions of E or 3D resulted from control incubations without added enzyme preparation in any of these buffers.

**Kinetic experiments.** NADH or NADPH concentrations were 5–336 µM and were obtained by addition of the appropriate amounts of NAD⁺ and NADP⁺, and a regenerating system consisting of 2.5 units of *L. mesenteroides* Glc-6-P dehydrogenase/ml, and 6.0 mM Glc-6-P. *L. mesenteroides* Glc-6-P dehydrogenase reacts with NAD⁺ and NADP⁺ at different rates, and the amount of enzyme added to the incubations was adjusted accordingly (i.e. 2.5 "NAD⁺ units" for incubations requiring NADH as cosubstrate, 2.5 "NADP⁺ units" for incubations requiring NADPH as cosubstrate). This regenerating system provided constant NADH and NADPH concentrations (within ±5%) during the incubations (monitored by u.v. absorption at 340 nm).

In the range of G-25 sup protein concentrations used, the reactions were linear for the duration of the incubations (10 min), and the reaction rates were proportional to the amounts of protein added.

The reciprocals of substrate concentrations and velocities were subject to linear regression analysis and a 2-tailed t-test. Only sets of data that resulted in a confidence limit of >99% were used for the calculation of the apparent kinetic parameters.

**Extraction, purification and HPLC analysis**

The reaction products were extracted, purified and analyzed by reversed-phase HPLC as previously reported (Weirich *et al.*, 1990a).

**RESULTS**

In the interconversion of 3α-hydroxyecdysteroids, 3xoeecdysteroids, and 3β-hydroxyecdysteroids five different enzyme activities can be distinguished (Fig. 1): ecdysone oxidase, NADH-dependent 3xoeecdysteroid 3α-reductase, NADH-dependent 3oxoeecdysteroid 3β-reductase, NADPH-dependent 3oxoeecdysteroid 3α-reductase, and NADPH-dependent 3oxoeecdysteroid 3β-reductase (Weirich *et al.*, 1990a). It is not clear at present whether the reductions are catalyzed by one 3α-reductase and one 3β-reductase, each displaying different kinetic parameters with each of the two nicotinamide adenine dinucleotide cosubstrates, or by four different cosubstrate-specific reductases. However, for the sake of simplicity they will be referred to as four individual enzyme activities with the cosubstrate shown in parentheses.
**Ecdysteroid 3-epimerization**

Fig. 2. Effect of pH on ecdysone oxidase (a), 3β-reductase (NADH) (b), 3β-reductase (NADPH) (c), 3α-reductase (NADH) (d), and 3α-reductase (NADPH) (e). Incubation mixtures contained 50 μM E (a) or 40 μM 3D (b–e), and G-25 sup [0.12 (c, e), 0.49 (b, d), or 2.14 mg protein (a)] in 1.0 ml of buffer and were incubated for 20 (b–e) or 120 min (a) at 30°C. Buffers were sodium citrate/phosphate for pH 5–7, sodium phosphate for pH 7–8, or glycine/NaOH/sodium phosphate for pH 8–10. Ordinate: pmol/min/mg protein.

**pH optima of enzymes and pH of midgut cytosol**

The pH optimum of ecdysone oxidase and 3α-reductase (NADH) was 7.5, the pH optimum of both 3β-reductases was 6.5, and the 3α-reductase (NADPH) showed dual pH optima below 5.3 and above 9.7 (Fig. 2). The pH of the midgut cytosol was 7.9.

**Kinetic parameters**

For further characterization of the 3-oxoecdysteroid 3-reductases the apparent kinetic parameters relative to the nicotinamide adenine dinucleotide co-substrates were determined. 3α-Reductase (NADH) and 3β-reductase (NADPH) showed Michaelis-Menten type relationships between cosubstrate concentrations and rates of reaction (Figs 3 and 4), but the other two reductases did not (Fig. 3). The kinetic parameters were $K_m = 80.8 \pm 10.8 \mu M$ and $V_{max} = 0.58 \pm 0.30$ nmol/min/mg protein for 3α-reductase (NADH), and $K_m = 19.3 \pm 2.5 \mu M$ and $V_{max} = 4.39 \pm 0.40$ nmol/min/mg protein for 3β-reductase (NADPH) (means ± SD, duplicate determinations from each of two separate experiments utilizing two different G-25 sup preparations). The

data for 3α-reductase (NADPH) and 3β-reductase (NADH) shown in Fig. 3, insert, might suggest that the cosubstrate concentrations used were too high and, therefore, the incubations failed to show a dependence of the reaction rates on the cosubstrate concentrations. However, other experiments conducted with lower cosubstrate concentrations (5-25 μM NADH or NADPH) also failed to show a Michaelis–Menten type relationship.

**Effects of NAD+ and NADP+ on 3-oxoecdysteroid 3-reductases**

Many oxidoreductase-catalyzed reactions are reversible and the rates can be influenced by the concentrations (concentration ratios) of the substrates and/or products. We, therefore, determined the effects of NAD+ and NADP+ (at 8.3 times the concentration of NADH or NADPH) on the two major 3-oxoecdysteroid 3-reductases (Table 1). 3α-Reductase (NADH) showed a 26% inhibition by NAD+, and a 100% inhibition by NADP+. 3β-reductase (NADPH) showed 6% inhibition by NAD+, and 96% inhibition by NADP+. These results suggested that NADP+ competes very effectively for the NADH binding site of the 3α-reductase and for the NADPH binding site of the 3β-reductase. NAD+, on the other hand, seemed to exert moderate competition for the NADH binding site of the 3α-reductase, but only marginal competition for the NADPH binding site of the 3β-reductase.

We also tested the reversibility of the 3-oxoecdysteroid reductions by incubating G-25 sup (2.2-3.5 mg protein/ml) with E or E' (25-50 μM) and NAD+ or NADP+ (each at 0.6 and 2.5 mM) for up to 120 min. Although initial experiments indicated that 3D was formed in small amounts in such incubations (Weirich et al., 1990b), these results could not be verified in later experiments, and the question of the reversibility of the 3-oxoecdysteroid reductions remains unresolved.

**Effects of NaCl on 3-oxoecdysteroid 3-reductases**

Sodium chloride had a very strong effect on the 3-oxoecdysteroid 3-reductases, especially the 3α-reductase(s) (Table 2). The NADH-dependent reduction of 3D was 50% inhibited in the presence of 0.2 M NaCl, but the same salt concentration elicited a substantial NADPH-dependent 3α-reduction that was undetectable in the absence of NaCl. The NaCl apparently changed the cosubstrate specificity or preference of the 3α-reductase and at the same time enhanced the total activity. At 2.0 M, NaCl completely inhibited all 3α-reductase activity. These results have been confirmed by experiments with a partially purified 3α-reductase preparation (unpublished results). 3β-Reductase (NADPH) was 17% inhibited by 0.2 M NaCl, and 2.0 M NaCl caused a 94% inhibition.

Incubation mixtures contained 25 µM 3D; 0.19 mg protein/ml of buffer B (pH 7.5), with NADH as cosubstrate; or 0.11 mg protein/ml of buffer C (pH 6.5), with NADPH as cosubstrate; and were incubated for 10 min at 30°C. Means ± SD of duplicate determinations.

DISCUSSION

In a previous communication we reported the apparent kinetic parameters of the five enzyme activities involved in ecdysteroid 3-epimerization in M. sexta midgut relative to their ecdysteroid substrates (Weirich et al., 1990a). The evaluation of these data led to the conclusion that 3-epimerization of 3β-hydroxyecdysteroids is accomplished by the combined action of ecdysone oxidase and 3α-reductase (NADH), with ecdysone oxidase being the rate-limiting enzyme and the 3α-reductase converting most of the 3-oxo intermediate to the corresponding 3α-hydroxyecdysteroid. This conclusion implied the assumption that the midgut cells contain predominantly NADH and very little NADPH. NADH/NADPH ratios in insect midguts have not been determined, but insect flight muscles have shown very high NADH/NADPH ratios (Candy, 1985). A low NADH/NADPH ratio (i.e. substantial NADPH content) in midgut cells would favor the 3β-reduction of the 3-oxo intermediate to the biologically active 3α-hydroxyecdysteroid, and in situ changes in the NADH/NADPH ratio could affect the balance between 3α- and 3β-reduction.

The pH optimum of 7.5 for ecdysone oxidase and 3α-reductase (NADH) was in good agreement with the pH optimum of 7.3 previously obtained for the complete E to E' conversion (Mayer et al., 1979), and was close to the pH (7.9) of the midgut cytosol. Among the five enzymes (activities) analyzed, ecdysone oxidase and 3α-reductase (NADH) seemed to be functionally best adapted to their physiological environment. This observation supports the conclusion that these two enzymes are dedicated to the 3-epimerization in midgut cells.

In the present study we undertook a kinetic analysis of the four 3-oxoecdysteroid 3-reductases by varying the concentrations of the nicotinamide adenine dinucleotide cosubstrates. These experiments showed that only the two major reductases, 3α-reductase (NADH) and 3β-reductase (NADPH), followed Michaelis–Menten type kinetics, whereas the other two reductases did not show significant changes in the reaction rates over a wide range of cosubstrate concentrations.

The Michaelis constants showed that the 3α-reductase required a four times higher cosubstrate concentration (80.8 vs 19.3 µM) for half maximal activity than the 3β-reductase (Table 3). The $V_{\text{max}}$ for 3β-reductase (NADPH) (4.39 ± 0.40 pmol/min/mg protein) was determined at a 3D concentration of 12.5 µM ($K_m$ for 3D = 17.7 ± 10.3 µM; Weirich et al., 1990a) and was, as expected, about one half of the $V_{\text{max}}$ previously obtained (10.7 ± 3.3 pmol/min/mg protein) with varying 3D concentrations and a constant NADPH concentration of 600 µM (30 × $K_m$). The $V_{\text{max}}$ for 3α-reductase (NADH) (0.58 ± 0.30 pmol/min/mg protein), similarly determined at a 3D concentration (25 µM) equivalent to the $K_m$ (30.7 ± 16.2 µM), was substantially lower than that found previously with varying 3D concentrations and a constant NADPH concentration of 600 µM (7.5 × $K_m$) (4.06 ± 2.20 pmol/min/mg protein). This difference is probably due to the variations in this enzyme activity between different midgut cytosol preparations (Weirich et al., 1990a).

Our results have shown a moderate inhibitory effect of NAD$^+$ and a strong inhibitory effect of NADP$^+$ on the two major 3-oxoecdysteroid 3-reductases. It is interesting to note that NADP$^+$ strongly affects 3α-reductase (NADH) whereas NAD$^+$ had only a marginal effect on 3β-reductase (NADPH). These inhibitory effects may be caused by competition of the oxidized cosubstrates for the

‡From Weirich et al. (1990a).
binding sites for the reduced cosubstrates on the reductases (product inhibition).

Previously we tested the potential of \( E \) for product inhibition of the 3β-reduction of 3D (Weirich et al., 1990a). 3D was either infused into incubation mixtures or formed from E by the action of ecdysone oxidase at a comparable rate. Although these incubations had a more than 1000-fold excess of E over 3D (E at 50 \( \mu M \), 3D in the nM range), no product inhibition was observed. \( E \) has been shown to exert weak (product?) inhibition on the complete reaction sequence from E to \( E' \) (Mayer et al., 1979), but it is not known whether \( E \)-inhibited ecdysone oxidase or 3α-reductase.

The apparent effectiveness of NADP+ for product inhibition of 3β-reductase at an NADP+ /NADPH ratio of 8.3 and the failure of E to cause product inhibition at a E/3D ratio of >1000 suggests that E does not compete with 3D for binding to free reductase, but NADP+ does compete with NADPH. In other words, the enzyme–cosubstrate complex formation probably precedes the binding of the ecdysteroid substrate to the enzyme–cosubstrate complex. Thus, our data are compatible with the assumption of an ordered bi bi mechanism with the cosubstrate binding to the free enzyme, and the ecdysteroid binding to the enzyme–cosubstrate complex. This has been shown to be the mechanism for 3α-hydroxy-ecdysteroid dehydrogenase from mouse liver cytosol (Hara et al., 1988), and 3β-hydroxy-Δ5-steroid dehydrogenase/3-keto-Δ5-steroid isomerase from bovine adrenals (Brandt and Levy, 1989). Future work will have to prove whether it is indeed the mechanism for the action of corresponding \( M. \) sexta midgut cytosol enzymes as well.

Incubations of G-25 sup with E or \( E' \) and NAD+ or NADP+ failed to produce significant amounts of 3D. Thus, the 3-oxoecdysteroid 3-reductase reactions were not reversible under our experimental conditions, although the inhibition experiments indicated that NAD+ and NADP+ bind to the enzymes. In contrast to these findings, reactions catalyzed by mammalian 3α-hydroxyecdysteroid dehydrogenases have been shown to be reversible (Penning et al., 1984; Hara et al., 1988).

Potassium ions (up to 100 \( \mu M \)) had little effect on the 3-epimerization when tested with a partially purified enzyme preparation (Mayer et al., 1979). In our present study sodium chloride (at 0.2 M) showed a very profound effect on one (some) of the enzymes, 3-oxoecdysteroid 3α-reductase(s). It inhibited the activity with NADH as cosubstrate by about 50% and greatly increased the activity with NADPH as cosubstrate (from undetectable to 3-times the initial activity with NADH). The enzyme protein(s) seemed to have undergone a structural change under the influence of the NaCl that favored binding of NADPH over the binding of NADH and at the same time enhanced the total enzyme activity. 3β-Reductase activity, on the other hand, was only moderately inhibited at 0.2 M NaCl, and the cosubstrate preference was not affected. These data show that in addition to the NADH/NADPH ratio and the NAD(P) + /NAD(P)H ratio, the concentrations of NaCl and perhaps those of other salts (ions) can change the balance between enzymatically produced 3β-hydroxyecdysteroids and 3α-hydroxy-ecdysteroids.
